5. Difficult and Dangerous Labors.—H. A. Miller states that the normal progress of labor should be interfered with only when the mother or the child seems to be in danger. Judgment of each individual case should be carefully formed, applying all the known methods for measuring the pelvis, and the size of the child's head, and placing special importance on the possibility of engagement or non-engagement as the result of pressing on the uterus, and using the finger in the vagina, and the paw-like grip over the child's head. Due consideration should be given to the fact that a competent obstetrician has previously had difficulty and has secured a dead child from high application of forceps. As labor progresses, the borderline cases must be so conducted and at such a place as to permit of a cesarean section in preference to an application of high forceps, in case progress is not satisfactory and there seems to be a reason for hastening delivery. These cases should be conducted largely by abdominal palpation, judging of the descent by this method in preference to frequent and, many times, unnecessary vaginal examinations. In the absolute indications for cesarean sections they should preferably be done as soon as the patient fairly enters labor, accepting as evidence of the opening of the os some slight vaginal discharge, or, if necessary, one examination. In the relative indications for cesarean section it should be done prior to the time that the patient shows an unusual degree of exhaustion and preferably prior to the rupture of the membranes. In elderly primiparæ the possibility of a senile uterus must frequently be the determining factor in deciding as to spontaneous delivery, high forceps and cesarean section. High forceps should be applied only in cases in which the surroundings of the patient do not justify an abdominal cesarean and in which the head is floating free from the pelvis. The physician must be prepared to accept an infantile mortality in excess of 15 per cent. with a maternal mortality equal to elective cesarean section, plus a not inconsiderable morbidity. Pubiotomies should be done only when sufficient assistance is at hand to prevent undue separation of the pelvic bones and in cases in which a very slight increase of the conjugata vera is known to be sufficient to permit the passage of a living fetus. Craniotomy has no place in obstetrics on a living child, and the physician should avoid putting himself in the position of having to sacrifice one life to save the other when both should have been saved.

6. Cesarean Section.—C. A. Stillwagen notes that cesarean section may be said to be indicated generally in all cases of maternal or fetal dystocia, in which other methods of delivery are extra-hazardous to either mother or child. Therapeutic abortion is often too lightly undertaken. It is sanctioned by law and medical opinion, but this fact tends to diminish the sense of responsibility and to cause some unjustifiable operations. Craniotomy is rather condemned in a living fetus; it is doubtful whether this procedure is less dangerous than some forms of cesarean section. From a surgical viewpoint, cesarean section would be the quickest, surest and cleanest method of procedure in placenta prævia and is indicated in all cases of central placenta prævia and in the partial type when the child is living and near term, provided adequate surgical skill is available and the patient's condition makes her a fair operative risk. It is also a valuable recourse in eclampsia, emptying the uterus quickly, lowering the blood pressure, improving the chances for the child, etc. It is indicated in primiparæ with rigid cervix or any condition involving delay or unusual trauma to mother or child. The field of cesarean section is widening.

8. Poliomyelitis in Norway.—F. Harbitz points out that poliomyelitis has been recognized in Norway as a distinct disease since 1820, sporadic cases having been reported. Epidemics have occurred in 1858, 1886, 1889, 1903, 1904, 1905, 1906, the earlier ones being local, the later ones extending over wider tracts of country. The Norwegian physicians regard it generally as an acute infectious disease and also contagious, which view is shared by the author, who gives facts supporting his belief. Of great interest are the abortive cases which are found to be just as contagious as the severer ones, and it must be supposed also that the infection can be spread by means of healthy bacteria carriers, which explains the long period of incubation sometimes noted. According to Norwegian experience, the route of entrance is the nose, throat, and alimentary tracts. The degree of infectiousness as a rule is not very great. No evidence has been found that food is a source of infection, nor that there is a coexistent infection of animals. The unexplained points are the prevalence of epidemics in certain years without reference to changed climatic conditions, the greater prevalence in the summer and fall, and in rural districts, and lastly, the varying degree of contagiousness in different epidemics. Notification, isolation, careful disposition of the patient's excretions and secretions, especially from the nose and throat, general disinfection of articles in contact with the patient, particular attention to the lighter abortive cases and possible carriers, and care as to the hygiene of school children, and even the closing of schools, are the precautionary measures that have been taken. As a rule these have been begun too late, but they seem to have helped to limit and stop the disease. The treatment of individual cases has been mainly symptomatic, and possibly of not much avail. Systematic investigation of the disease is now being carried on.

12. Palliative Treatment of Terminal Laryngeal Tuberculosis.—H. Horn recommends as a palliative measure in cases of terminal laryngeal tuberculosis the Hoffman method of injecting the superior laryngeal nerve so as to produce a permanent anesthesia. The emaciation which is usually present makes the procedure generally an easy one. The point of entrance of the nerve through the thyrohyoid membrane can be palpated with exactness. The exact technique of making the injection is as follows: The skin is first prepared by painting the region to be injected with iodine. The left side of the larynx is grasped with the first and second fingers of the right hand, and with the thumb of the same hand the painful point is located. As soon as this spot is found the thumbnail is pressed in to mark the spot and the needle is introduced at this point. The needle is introduced perpendicularly for 1.5 c.m.; then the point is moved in all directions until a sharp pain, radiating to the ear, is felt. From 3 to 5 c.c. of a warm solution of 85 per cent. alcohol are then injected until the pain in the ear disappears. The point of entrance of the nerve will be found just at the upper edge of the thyroid cartilage, about one-third of the distance from its outer edge. In no case has the author had any untoward effects and claims that the procedure is entirely without danger. There is immediate relief from pain as the aspiration of food is seldom observed. The injection can be repeated without danger as often as necessary and the relief lasts from a few hours to forty days. The mental effect on the patient is a very important secondary one. He becomes more cheerful and tries to take food. In three cases the results were negative, and if there was an involvement of the epiglottis, especially on the external surface, it was found that the relief failed or was only partial.

2. Gray Hair Associated with Nerve Lesions. G. L. Cheatle.
3. The Treatment of Tabetic Ataxia. J. G. Garson.
4. A Note on the Morphology of a Strain of Trypanosoma Equiperdum. W. Yorke and B. Blacklock.

1. Intraneural Injections of Alcohol.—O. May concludes that alcohol, injected into the trunk of a peripheral nerve, produces a more or less complete local necrosis of the nerve at the point of injection. The change is not an "ascending" one, the nerve above the point of injection remaining normal; the cells of origin of the fibers may show some degree of chromatolysis, but do not exhibit signs of permanent injury. The conditions produced by such injection are more favorable to regeneration than those resulting from simple section without suture. The anatomical continuity of the nerve trunk favors rapid regeneration, though this is to some extent retarded by the fibrosis which occurs to a greater or less extent in every case of alcohol injection. It is apparently impossible by a single injection of alcohol to produce complete necrosis of the Gasserian ganglion, its dense texture preventing complete infiltration. The alcohol tends to find its way under the sheath of the ganglion towards the proximal root, which is affected to a greater degree than the actual ganglionic.

2. Gray Hair Associated with Nerve Lesions.—G. L. Cheatle notes the following observations that he made on the case of a male patient, aged 36 years, who had subcutaneous neurofibromata growing on the cheek and forehead of the right side, which were noticed about the same time ten years ago, when the hair also began to grow gray. The state of the grayness of hair was as follows: On the mid-orbital maximum point of Henry Head, there was a patch of normal brown color, which appeared as an island in a completely gray V-shaped area behind which, and limited behind by the posterior boundary of the fifth nerve, was an area of scattered gray hairs. There was no disturbance of sensation. Tactile, heat, cold, and pain sensations were normal. The author believes it would be of theoretical and practical interest to discuss the state of grayness of hair, together with the protopathic nerve influence described by Head. The discussion would be very discursive, owing to the fact that one's knowledge is not sufficient to enable one to state what makes hair appear gray. The author believes that the above case illustrates an epithelial change in state, which takes place *pari passu* with a change in the nervous system, and, therefore, probably due to it. Although grayness of hair is of itself an unimportant epithelial change, it appears at a time of life common to another and important epithelial change—namely, cancer. The genesis and etiology of an unimportant change in a tissue may illuminate

the genesis and etiology of an important change in the same tissue. Grayness of hair may be said to be a degenerative change and cancer a proliferative change. The proliferative change in cancer can hardly be considered an object lesson in regeneration; its products are nearer degeneration products, so far as size, shape, and function of the cells are concerned.

Traumatic and Chemical Injuries of the Nervous System.—Zweig gives a digest of the literature of this subject for the second half of the past year. It has been abundantly shown by recent statistics that accidents determine or aggravate many conditions which usually come about without such a casual moment. Among these affections are lues cerebri and the metalnetic affections of the central nervous system, manic-depressive insanity, and catatonia. Naturally proof of the relationship may be difficult, but the number of times injury to the head is followed by some of these manifestations cannot be due to coincidence. A bad encephalopathy menacing a patient may come about after an injury. The possible part played by traumatic hemorrhage in all such cases is important, for in such an event there would be no period of latency. Again, if a period of latency were present, the condition could still he due in part to secondary hemorrhage. Psychoses which are the result of injury alone—so-called traumatic psychoneuroses—are distinguished from the preceding by the presence of the psychic trauma and the hysterical character of the symptoms. In still another category should be placed the mental disorders which result without any predisposition from the severity of the injury. Here belong delirium, twilight states, and primary traumatic dementia. There is a decided parallel between these results and physical shock and the same phenomena when occurring in alcoholics and epileptics. Injuries to the head may also produce peripheral manifestations and vasomotor syndromes and peripheral injuries may react upon the central nervous system. The expertisation of casualties in reference to responsibility appears to grow more difficult and complicated with medical advances. In reference to so-called chemical injuries of the central nervous system the chemicals chiefly in evidence are carbon monoxide and the lead salts with nicotine, morphine, and cocain. Tobacco undoubtedly frequently cooperates with other agencies in causing individual disease pictures. Experience shows that drugs do not alter the psyche for the germ of the alteration preexists in the hereditary degeneracy of those who are addicted to drugs.

Menstrual Insanity.—König relates a case which he places under this head. The patient, aged 38 and of sound habit and stock, had been submitted to double craniotomy. The supposed indication is unknown. For a time following the woman became forgetful and irritable. The menses were not wholly suppressed, probably because extirpation of the ovaries had been incomplete. She now began to show distinct changes of disposition at the menstrual epoch and in the course of about three years suddenly developed suicidal and homicidal tendencies. The latter, however, were rationally conceived, for the woman's husband had seduced his own small daughter and the woman's desire to take the lives of her children culminated in the death of one of them and an attempt on her own life and that of her other child. Admitted into the asylum, the patient exhibited for six years the premenstrual alteration of character, but was otherwise normal. These cases are as a rule complicated in character. In addition to the predisposition afforded by the psychophysical inferiority of the premenstrual period, there were present the element of the artificial menopause and the effects due to the family life, hoth of which may have been exciting causes.

Treatment of Cancer with Internal and External Remedies.—Zeller gives some of Czerny's experiences in the non-operative treatment of cancer during the past seventeen years. The latter's policy has been to test old empirical procedures. The type of cancer treated natually consisted largely of superficial growths. The aim has not really been to supersede the knife, but to supplement its use when operation was refused or when for any reason the case seemed inoperable. One of the old remedies tested internally was silicic acid. One patient with a malignant growth on the nape of the neck recovered in six weeks of this treatment. The woman had refused operation. The woman is still living after seventeen years. A similar result was obtained in two cases of cancer of the breast. In all these cases in the absence of a trial excision the diagnosis was in some doubt. In a fourth case, a cancerous ulcer of the face with diagnosis not open to doubt, the ulcer healed very slowly, some two years having been required. Patient took only 45 drops daily of a solntion of silicates of potash and soda. The woman is living and carries a radiating scar. Among other successful cases was one of multiple scirrhus of the breast. There were in all during the period 1895-1906 nine remarkable cures attributable to the silica. In every case there was clinical malignancy. At the expiration of the period a synthetic containing silica was devised for injection. It was an ester and contained 13 per cent. of the element. A solution in olive oil was injected into the muscles and in every case tested an accurate diagnosis was made and an attempt was made to attack cancer without so much selection. Twenty-five cases were treated during 1906-1909 without a single positive result, evidently because the elapsed time is hardly sufficient. On the other hand, the improvement which followed the injections was pronounced. The results were at the most arrest or diminution in size. Since 1909 the author, whose work had been interrupted by illness, returned to his crusade and concluded that cancers which had begun to show regressive change were not eligible to the silica treatment. The apparent specific action of the drug on the dying cancer cells may even increase the cachexia which is conceivably due in part to slow ptomaine poisoning. He therefore treated a series of young cancers with silica alone and conceived the notion of anticipating the cancer necrosis or removing its products by using the old arsenical paste. In a very considerable number of cases with the reserve force of the local treatment he has achieved a large body of apparent cures, the observation period being naturally too brief for remote results. The author appears to have no doubt that silica is the most efficacious chemotherapeutic remedy against the cancer cell.

Trendelenburg on American Surgery.—Trendelenburg seemingly representing German surgeons, makes adverse comment on a recent paper by Kehr on duodenal ulcer in which the latter, unable to explain the great frequency of this lesion in the Mayo clinic, was led to theorize erroneously. Trendelenburg gives a brief résumé of the work done at this clinic and implies that the frequency of duodenal ulcer is accounted for amply by factors other than those assigned by Kehr, these including a sort of operating craze not only on the part of the surgeons but even the public. Points made by Trendelenburg are the great area drawn upon by the prestige of the clinic, the personnel of the patients who are made up very largely of vigorous rural dwellers able to withstand intervention, the cooperation of a large number of specialists in both diagnosis and operative technique, and the host of medical visitors who, after witnessing the work of the clinic, naturally become enthusiasts in referring patients thereto who suffer from certain symptoms. The cases treated are pre-

eminently borderline in character—medicosurgical. Trendelenburg concludes that the Mayo clinic must from its very momentum become a great special academy for instruction in these cases, if indeed it be not one already.

Amenability of Herpes Gestationis to Serum Therapy.—Veiel refers to our former knowledge of this condition, its refractoriness to treatment and persistence until after delivery. One of the great triumphs of the theory and practice of serotherapy was the discovery but two years ago that a pregnancy serum is able to cure this eruption outright. A similar advance in our knowledge of the gestation toxicosis is likewise secured, for we are now amply justified for this and other reasons in speaking of an autotoxic state dependent on pregnancy. As is well known to dermatologists, there are two closely related toxic dermatoses of gestation. One of these is very rare and malignant—the so-called impetigo herpetiformis. The other or benign type is the so-called herpes gestationis. The malignity of the first named is due to its progressive character and the impossibility of antagonizing it. Whether serotherapy can arrest this form we do not know because its infrequent occurrence gives no chance to test the resource. The controllability of the milder form is complete. The itching, which is the most burdensome symptom, ceases promptly under the treatment. The latter is simplicity itself. Blood serum is obtained from a healthy pregnant woman and 10 c.c. are injected subcutaneously in the gluteal region. The serum was from a gravida at the ninth month.

Biological Significance of Eosinophile Substance.—Petry concludes in reference to the eosinophile cell granules that they do not possess bactericidal or antitoxic qualities, nor are they themselves toxic to animal life. They certainly do not represent the sole of leading substance which produces the Charcot-Leyden crystals. They contain a substance which gives the indophenol synthesis. Upon the autodigestion of the leucocytes the granules pass into solution. When injected under the skin they are taken up by fibroblasts and dissolved and later are disintegrated to granular iron pigment. In the bone marrow entire granules are transformed outright to iron and, generally speaking, this metamorphosis represents a storage of iron for future use. Iron thus occurring may come into use as a product of internal secretion.

Familial Incidence of Hodgkin's Disease.—Braun states that such incidence is extremely infrequent. Recently new documents have been adduced to show that the disease in question is a sort of metatuberculosis; and the author is able to report a series of three cases in a tuberculous family. The first patient was a woman aged 55, naturally sound, who developed a general sarcomatosis of the bones; or at least such was the diagnosis at the time. The patient died after seventeen months of illness. Her brother, a few years younger, and himself a practicing physician, was healthy until attacked by a condition diagnosticated malignant lymphoma, which ended his life in three and one-half years. A third member of the same family, male, and still younger, developed multiple lymphoma of all the palpable lymph nodes. Diagnosis was in doubt, as it lay between leucemia and Hodgkin. After death the latter was made plain. The relationship of the disease in the different members of the family was undoubted, showing further that generalized sarcoma may be regarded as an equivalent of pseudoleucemia. A study of the family showed that originally there were ten children, two of whom died in childhood. The others were all raised and were unusually robust. Only one died before middle age (apoplexy). There was notable freedom from scrofula and tuberculosis. The father, paternal grandparents and great-grandparents showed a notable absence of longevity, but seemingly no tuberculosis. The mother and ascendants were unusually vigorous and longlived. Nevertheless, there was a familial taint present, as shown in the collaterals on both sides. There were not a few deaths from consumption. There was also consanguinity in some of the unions. When the entire trees were written out it could be seen that the stock was honeycombed with tuberculosis, expressed in all the usual forms—pulmonary consumption, galloping consumption, bone tuberculosis, and scrofula. This was often marked by the fact that the subjects lived to a good age even while victims of hip disease and quick consumption.

August 29, 1912.

Collargol in Sepsis and Carcinoma.—Kausch sums up several years of personal experience as follows: Intravenous injections of collargol cause the cessation of septic fever with all its accompaniments. This action is so certain that should it fail we are safe to assume the existence of virulent foci of pus. The same efficacy is seen in pyemia when after evacuation or drainage of the pus the fever persists. If exacerbations occur further injections are practised. The usual dose is from 10 to 25 c.c. of the two per cent. solution. In severe cases this dose may be increased to 50 and even 100 c.c. This treatment has been employed in many forms of sepsis and septicopyemia. It has also been practised in a number of cases of inoperable cancer, but the time limit for final results is not yet due. For the present it can only be claimed that a favorable local and constitutional reaction is engendered. Of five cases described in detail all are doing well considering the nature of the symptoms, the patients being in cachexia from the inoperable cancers. Although the general reaction was severe it led to no injurious consequences and after the reaction the general condition seemed notably improved. The inference is perhaps that the factors, whatever they are that make for the cancerous cachexia, are antagonized by the collargol.

Why Is 70 Per Cent. Alcohol so Strongly Bactericidal?—Frey has shown that 70 per cent. alcohol is the optimum for bactericidal purposes. Stronger as well as weaker concentrations are alike inferior. This property seems to be due to the action of alcohol on albumin, for at the said concentration the latter is most completely coagulated. The thirty per cent. of water is naturally responsible for the optimum of coagulability, which is not fixed at 70 per cent., but ranges between 60 per cent. and 70 per cent. The coagulating action would doubtless increase with the alcohol content of a mixture, but another element, the distribution of the alcohol upon the colloid, enters into the results and fixes the optimum limits.

Nature of Chronic Dacryocystitis.—Rhese states that in very many cases this condition is conditioned by ethmoidal disease. The anterior ethmoidal cells have the same significance for the lacrymal sac as the posterior portion of the bone possesses for the orbit. The prognosis for dacryocystitis of this causation is excellent, and the ethmoidal operation will prove curative in very obstinate cases with early formation of fistula. In other diseases of the tear passages of rhinogenous origin, the middle meatus has a greater significance than the inferior meatus. In establishing a diagnosis of rhinogenous affections of this sort the *x*-ray furnishes valuable aid.

Vasodilator and Vasoconstrictor Properties of Blood.—H. A. Stewart and S. C. Harvey state that the blood contains a vasodilator substance specific for the renal vessels. During clotting there is liberated a constrictor substance that acts on the renal vessels and those of the limb. The former substance is a proteid; the latter is not. They both act directly on the muscle coat.—*Journal of Experimental Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE URINE.

Technique of Urinalysis.—Avoid mistakes by exercising painstaking care at each step and taking sufficient time, especially if there is the slightest doubt.

Keep all apparatus scrupulously clean, and wash the beakers and tubes thoroughly before and after using for each specimen of urine.

Remove all stains and smears from the test tubes. Nitric acid will remove tenacious stains from the inside of the tubes.

During the process of boiling the tube may become sooty, or cloudy from the salts remaining after the evaporation of moisture from the outer surface of the tube; in either case the tube should be gently cleansed with a damp cloth before inspection of the contents.

Do not employ the same tube for both the albumin and sugar tests, as the reagents employed for detecting sugar often leave deposits on the inside of the tubes which are difficult to remove.

Small amounts of albumin readily escape detection in semi-opaque, dirty tubes.

Turbid urine must be filtered before making the chemical analysis; otherwise traces of albumin will not be discovered. It may be necessary to filter the specimen several times, but if it still remains turbid after this procedure, bacteria or pus is probably present and a fresh specimen should then be obtained. Do not filter with the aid of powdered talc, French chalk, charcoal or any other powder. These insoluble powders often remove the turbidity, but they also remove considerable amounts of albumin and sugar.

Tests should not be made or read by artificial light.

Reaction.—This is ascertained by the litmus paper. Acids turn blue litmus paper red, while alkalies turn red litmus paper blue. Occasionally a urine will be amphoteric, in which case it turns red blue and blue red. This condition is of no significance.

Specific Gravity.—The urinometer must float clear in the urine and not come in contact with the walls of the tube. The limits adopted by most companies are 1,010 and 1,030, and if the specific gravity falls outside of this range the examiner is expected to obtain another specimen and subject it to a complete chemical analysis.

Tests for Albumin.—The use of the albumoscope or horismanscope is not recommended.

Do not use that portion of the urine to which the heat test has been applied, for the cold nitric acid or contact test.

Always hold the tube against a black background by a well-lighted window in order to observe accurately the result of the test in either method.

Having thoroughly cleansed the tube and filtered the urine, if necessary, the following tests are to be used, as they are the most reliable and convenient:

HEAT TEST. A clean test tube is filled two-thirds full of clean urine. If not acid it should be made so by the addition of one or two drops of acetic acid or dilute (10 per cent.) nitric acid. Boil the upper half of the urine for half a minute at least, holding the tube by its lower end and taking care that it does not become sooty. Then hold the tube against a black background by a well-lighted window.

If there is no sign of turbidity in the upper boiled part as compared with the lower cold part, there is no albumin in that specimen.

If there is any turbidity in the upper boiled part, add two or three drops of nitric acid. If the turbidity entirely and promptly clears up, it was probably due to earthly phosphates and it can still be said the urine is free from albumin.

If any turbidity, no matter how slight, remains after the addition of nitric acid, it indicates the presence of albumin or nucleo-proteid, probably the former. To differentiate between these, the examiner must resort to Heller's test.

If the heat test gives absolutely no reaction, it can safely be said that the urine contains no albumin and it will not be necessary to resort to Heller's test.

Some recommend the addition to the urine of one-sixth its volume of a saturated salt solution before adding any acid or applying heat.

HELLER'S TEST. Pour half an inch of pure, colorless nitric acid into the tube. The test tube is then held at an angle of more than 45 degrees while a quantity of clear urine is allowed to flow from a pipette slowly down the side of the tube until an inch of it overlies the acid. If this is carefully done there will be no mixture of the urine and acid. When albumin is present it will be indicated by a sharp, white ring at the line of contact between the acid and the urine.

This white zone may form very slowly when the albumin is present in a small amount, and it is therefore imperative for the tube to be set aside carefully for at least *fifteen minutes* in order to get a positive reaction with traces of albumin.

A diffused ring or cloudiness beginning above the line of contact indicates urates or nucleoproteid, but not albumin. This diffused ring need never be confused with the sharply defined albumin ring at the line of contact.

A positive reaction with both the heat and Heller's test indicates without doubt that albumin is present; it is equally certain that no albumin is present if Heller's test carefully carried out according to the directions gives a negative result, even though a cloudiness remains after application of the heat test.

If the person has been taking any oleoresin, such as cubebs, copaiba, etc., this will also cause a white ring at the junction of the liquid, but it can easily be differentiated from albumin by means of the heat test.

Another method, requiring considerable care to prevent mixture of the urine and acid and not advised for this reason, is the following: Take a perfectly clean, dry test tube and place in it about one inch of urine; allow concentrated nitric acid to flow slowly from a pipette down the side of the inclined test tube. Wait fifteen minutes, then look very closely for a wide band or cloud denoting albumin just above the junction of the acid and the urine.

A Plurality of Examiners.—At the annual meeting of the Proctologic Society, the president, Dr. John L. Jelks, said that attention was now being paid by life insurance examiners to conditions in the rectum. He said he was often consulted by examiners concerning the existence of diseases of special organs or regions and he thought alert medical referees were considering the advisability of subjecting applicants for large policies to a plurality of examiners.

Book Reviews.

FORSCHUNGEN UND ERFAHRUNGEN, 1880-1910. Eine Sammlung ausgewählter Arbeiten von Prof. Dr. Sir FELIX SEMON, K. C. V. O., Fellow of the Royal College of Physicians; Vice-President and Consulting Laryngologist of the International Hospital for the Paralyzed and Epileptic; Physician Extraordinary to His Late Majesty King Edward VII, of Great Britain and Ireland. 2 volumes; price 32 Marks. Berlin: August Hirschwald, 1912.

THESE volumes are dedicated by Sir Felix Semon to his friend, Sir Victor Horsley, F.R.S., "in constant gratitude for his invaluable collaboration in the physiological portion of the work."

In presenting a collection of thirty years' work, the author feels that an explanation for its appearance is necessary, and this is forthcoming when the inaccessibility of some of the original journals of publication is mentioned, as, the Proceedings of the Royal Society of the Academy of Sciences; of the Royal Institution of Great Britain; Virchow's Festschrift; the *Archives of Laryngology*, etc., as also from the fact that the articles have appeared in various languages. The subjects are not arranged in accordance with their time of appearance, but in their relation to each other, so that the first 400 pages are devoted to the writer's work on the physiology, pathology, and history of the study of the laryngeal nerves.

It was especially fortunate that the then comparatively untrodden field of laryngology possessed so steadfast and earnest a worker as Semon, and it is of special interest to note that the result of that work of his in connection with Horsley has so well stood the test of time that the conclusions then drawn have since become firmly established and fixed as laws.

In the second volume, reprinted from the *Internationales Centralblatt für Laryngologie*, he tells the story of the disease of Emperor Frederick, of Germany, in its relations to laryngology. This is remarkably interesting reading and one can feel the extremely delicate position in which the author found himself in describing the bitter controversy which was without doubt the most disagreeable quarrel of modern times among medical men.

Further contributions from the pen of this author are on malignant and benign growths in the larynx as also various septic invasions of the upper air passages. The volume concludes appropriately enough with a chapter on the relation of laryngology and rhinology to allied scientific bodies; for those who have followed Semon's career know how earnestly he has fought for the proper position of laryngology in the scientific world, so that the quotation at the beginning of the first volume, "To live is to battle" seems eminently proper in this connection.

To those interested, this collection of the works of the distinguished author will be of exceeding value, our only regret being that it will be inaccessible to many of our English and American confrères who are not familiar with the German language in which it is printed.

The two volumes are in stately form and a perusal of their contents again giving an indication of the intrepidity possessed by the wielder of this facile and at times trenchant pen, makes us once more regret the loss that laryngology has sustained in his retirement from the field of active work.

PSYCHOTHERAPY, Including the History of the Use of Mental Influence, Directly and Indirectly, in Healing and the Principles for the Application of Energies Derived from the Mind to the Treatment of Disease. By JAMES J. WALSH, M.D., Ph.D.; Dean and Professor of Functional Nervous Diseases and the History of Medicine at Fordham University School of Medicine, and of Physiological Psychology at the Cathedral College, New York; Fellow of New York Academy of Medicine; Member A.M.A., A.A.A.S.; New York State Medical Society, German Society for the History of Medicine and the Physical Sciences, New Orleans Parish Medical Society, St. Louis Medical History Club, etc. New York and London: D. Appleton & Company, 1912.

THIS work represents the first ambitious attempt to write a textbook on psychotherapy covering every phase of the subject not only with reference to functional and organic diseases of the nervous system but also with reference to all diseases, including those of nutritional and microbic origin. Psychotherapy is as old as the healing art itself, and whether practised unwittingly as it has been by innumerable physicians, or whether it is deliberately made a part of modern methods of treatment, this form of therapy has demonstrated its value to such an extent as to warrant the presentation of a comprehensive treatise on the subject. The author has demonstrated by his numerous scholarly writings on the history of medicine and his neurological training that he has been eminently equipped to write a volume of this kind. The first part of the work deals with the history of psychotherapy under the following headings: great physicians in psychotherapy; unconscious psychotherapeutics; genuine remedies and suggestive exaggeration, signatures and psychotherapy; pseudoscience and mental healing; quackery and mind cures; nostrums and the healing power of suggestion; amulets, talismans, charms; deterrent therapeutics; influence of the personality in therapeutics; and faith cures. The second part of the work discusses the subject of general psychotherapeutics under the headings of general considerations, the individual patient, the general principles of psychotherapy and adjuvants and disturbing factors. Among the subjects presented in this division are the mutual influence upon each other of body and mind, unconscious cerebration, the daily occupations and diversions of patients, habit, and pain. The next section of the work deals with special psychotherapy or psychotherapy in various disease conditions such as constipation, heart disease, tuberculosis, rheumatism, dysmenorrhea, sexual neuroses, skin diseases, diabetes, paresis, neurasthenia, etc. The concluding part of the volume deals with the disorders of the psyche. Some of the topics discussed in this section are the psychoneuroses, insomnia, disorders of memory, alcoholism, grief, and responsibility and will power. There is a special section on psychotherapy in surgery, and there are appendices on illusions and religion and psychotherapy. In detailing the above topics the reviewer desires to call attention to the extraordinary scope of this method of treatment, which is not confined solely to diseases of nervous or functional origin but penetrates into every domain in medicine; even those diseases that are incurable, such as advanced cancer, deriving some benefit, however slight, from the ministrations of a tactful and sympathetic physician. The author has brought to his task in writing this book a wealth of information which only a ripe practical experience and extensive reading of ancient and modern literatures can provide. Although one may differ with the author in certain of his views, for instance as to the efficacy of faith cures, there can be no question that he has written an eloquent brief for psychotherapy. The general practitioner will undoubtedly find something in this volume that will help him in his daily work.

TASCHENBUCH DER KLINISCHEN HÆMATOLOGIE. Von Dr. von DOMARUS, Assistant an der II medizinischen Klinik in München. Mit einem Beitrag: Röntgen behandlung bei Erkrankungen des Blutes und der blutbereitenden Organe, von Prof. Dr. H. RIEDER, und einer farbigen Doppeltafel. Price 4 marks. Leipzig: Georg Thieme, 1912.

IN this very excellent little volume of 200 pages the author has presented the essentials of clinical hematology concisely but with sufficient explicitness for most purposes. The technique of cell counting, hemoglobin determination, and the examination of stained and unstained films is described clearly and with a discrimination in the selection of methods with which the reviewer very heartily agrees. Unlike most German hematologists, Domarus is satisfied with two stains for routine use, the Jenner (which he, of course, calls the May-Grünwald) and the Giemsa, which two he justly says suffice for all ordinary purposes. His discussion of the origin of the blood cells is also especially commendable in its simplicity and he wisely does not align himself with either the followers of Poppenheim who assumes that lymphoblasts and myeloblasts are identical or with those of Naegeli and Schridde, who contend that they are distinct, but states that the question must still be considered an open one. The sections on the clinical manifestations of the various anemias, etc., are equally admirable, and the brief references to therapeutic procedures are interesting as embodying the teaching of the celebrated II medical clinic of Munich. In regard to the application of transfusion to the treatment of severe anemias he is of the opinion that the effect probably does not depend on the amount of blood introduced, but rather on the stimulation of the bone marrow induced. For this purpose small amounts (5 c.c.) taken from the donor with a syringe and injected directly without defibrination into the vein of the recipient may be used. Prof. Rieder contributes a short chapter in which the Röntgen ray treatment of lymphatic and myelogenous leucemia, of pseudoleucemia, Hodgkin's disease, polycythemia with splenic enlargement, and tuberculous lymphoma is advocated. The book is exceedingly satisfactory and deserves the warmest commendation.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-eighth Annual Meeting, Held at Boston, Mass., May 30-June 1, 1912.

Dr. E. W. Taylor of Boston, Vice-President, in the Chair

(Concluded from page 500.)

Friday, May 31—Second Day.

Some Atypical Forms of Tabes and Paresis Considered in the Light of Sero-Diagnosis.—Dr. C. Eugene Riggs of St. Paul read this paper reporting four irregular cases of tabes and one of general paralysis. In none of these were the classical, clinical symptoms of tabes or paresis present. Knee-jerks and Argyll-Robertson phenomenon were wanting in all the tabetics. Lightning pains were present in two; lymphocytosis in only two cases. The blood serum gave two negative Wassermanns; the same was true of cerebrospinal fluid. The globulin reaction was positive twice. In the case of paresis the mental symptoms resembled the depressive phase of manic-depressive insanity rather than paresis. All four reactions almost invariably present in paresis (Nonne) were positive. Later dementia seemed imminent, but the patient made an apparent recovery; this was most probably a remission.

Dr. E. D. Fisher of New York said that serodiagnosis was of great value. In the psychopathic wards in Bellevue Hospital, New York, the diagnosis of general paresis was often very difficult to make from a clinical standpoint when it was combined with syphilis and there was a history of alcoholism. It might take several months of observation before a positive diagnosis could be made. It was in just such atypical cases as Dr. Riggs had said that this method of examination was so important.

Dr. Russel of Montreal said that the Wassermann reaction in his experience had not been altogether satisfactory. He had been led to place very little dependence upon the Noguchi globulin reaction. He placed more confidence in the lymphocyte test and was guided in the administration of salvarsan by the findings of this.

Induced Paralysis; Its Therapeutic Application in a Case of Tic.—Dr. Sidney I. Schwab of St. Louis read this paper, in which he stated that the injection of alcohol in the nerve produced acute paralysis. After a number of months there occurred slow progressive return of function, due to regeneration of nerves temporarily blocked or excluded from activity. Concerning the theory of tic movement the psychogenetic origin must be removed. Nevertheless there were certain cases that were absolutely untouched by any of the well-known methods now in use. It was for this class of cases that the procedures described by Dr. Schwab were devised. The tic movement is so embedded in the patient's consciousness that it makes him unable to carry on his work. The man to whom Dr. Schwab referred was a man of minor intelligence who worked in a bristle factory. He had to tie the bristles in bunches ten hours a day for ten years steadily. The tic movement consisted of extension of the fingers and thumb, and the arm was then thrown clear from the body and grasped with the right hand. Among other forms of treatment the Rolandic area was exposed in 1908, but nothing was found. On the 21st of October, 1909, injection was made into the spinal accessory, median, and ulnar nerves with 80 per cent. alcohol. This produced flaccid paralysis. In May, 1910, the first return in voluntary muscular power was noted. It seemed reasonable to assume that the tic movement would not return even though function should return.

Dr. Hugh T. Patrick of Chicago said he was very glad indeed to have Dr. Schwab's favorable report. Believing as he did that tic and spasm were so totally distinct and separate, he had never had the courage to inject tic for the reason that tic, if stopped in one place, was very apt to come on in another, as all the patient's own devices for stopping it showed.

Dr. L. Pierce Clark of New York stated that two or three years ago he saw a case of tic of the neck and advised the surgeon not to do any operation, but the surgeon went ahead and did the alcohol injection, and, singularly enough, got good results. Dr. Clark believed that these tics are to be judged as mental factors. One should not concern oneself with the particular kind of movements, as the whole individual needs training for giving the proper degree of mental balance.

Preliminary Report Upon a Hitherto Undescribed Type of Familial Palsy.—Dr. L. Pierce Clark of New York presented this communication in which he detailed the histories of nine members of a family of nineteen individuals of four generations who presented life-long attacks of motor disability or palsy resembling family periodic palsy. His cases were differentiated from the latter affection in that the disability attacks were unattended by electrical or deep reflex alterations and in that the cranial nerves and some involuntary muscles showed loss of movement. There was an inherent muscular defect akin to pseudomuscular dystrophy in some of the members of the third and fourth generation and severe acetonuria in several children of the fourth generation, the same followed by death in one child. All the individuals afflicted with disability attacks were females excepting one, the great-grandfather with whom the disease apparently originated. One girl of four, of the fourth generation, who had just developed the disease, also suffered from severe acidosis, being the first member to show an association of the two diseases in the same individual. The disability attacks in the several members of the different generations occurred at irregular intervals of days, weeks, or months. The attacks were indifferently mild and severe, occurred more or less abruptly, and affected the finer voluntary movements in the lower extremities chiefly. The author has had several members of the family under observation for a period of several years and was inclined to consider the disorder to be due to an inherent muscle anomaly upon which unknown toxic metabolism was superimposed at the time of actual attacks. Psychic factors of various sorts: fear, mental fatigue, and emotional stress, were also regarded as determinant of the attacks. The author regarded the type as one of the many forms of hereditary familial palsy nearer in kin to the dystrophies than to family periodic palsy.

Dr. Dana of New York said he did not see exactly why Dr. Clark had settled on such a group of cases as being of different type or distinct from the ordinary family periodic paralysis. The description of his cases fitted perfectly with the group that Dr. Dana had studied, except that the attacks of paralysis in Dr. Dana's cases lasted from one to three days. He did not think that the absence of reflexes or electrical reactions was a criterion of any importance. Dr. Dana said he might not have appreciated all the points Dr. Clark had made, but he would say these were simply one of the minor types of the ordinary periodic paralyses.

The Etiological Relation of Syphilis to Aran-Duchenne Muscular Atrophy.—Dr. William G. Spiller of Philadelphia read this paper. He said that comparatively few writers had considered syphilis in the etiology of the various forms of spinal muscular atrophy, and the evidence offered by those who had done so had not been generally accepted. The writer had reexamined for evidence of syphilis ten cases with necropsy, embracing typical clinical types of amyotrophic lateral sclerosis, lateral sclerosis, and progressive spinal muscular atrophy, and had found some lymphocytic infiltration of the pia in most of the cases. He had recently studied two cases of cerebrospinal syphilis and one case of tabes with typical Aran-Duchenne atrophy, *i.e.* atrophy confined to the hands and forearms, and one of each of these types was with necropsy and microscopical examination. In these two cases marked degeneration of the cells of the anterior horns was found. If syphilis of the nervous system were suspected lymphocytic infiltration of the pia should be present in a considerable number of cases, as it was found frequently in tabes. It was not pathognomonic. In some cases thickening of the blood-vessels should be expected, but not as frequently as lymphocytic infiltration. Lymphocytosis of the cerebrospinal fluid was important as an evidence of syphilis.

Dr. McCarthy of Philadelphia said that without some other evidence he thought the view proposed by Dr. Spiller should not be accepted.

Dr. Starr of New York said that Erb's statement in regard to the syphilitic causation of locomotor ataxia was substantiated by showing definitely that the percentage of locomotor ataxia in those who had syphilis was far greater than the percentage in other diseases. If Dr. Spiller's statements were to be accepted he should show that a large percentage of patients suffering from amyotrophic lateral sclerosis were the subjects of syphilis. Dr. Starr said he recalled perfectly well three cases treated for some years for amyotropic lateral sclerosis in all of whom a history of syphilis was obtained.

Dr. Southard of Boston said he was inclined to think that one should not assert lues on the basis of leucocytosis. It was well known that anterior poliomyelitis showed lymphocytosis in a particularly characteristic way. Tuberculosis of the meninges showed it. He had seen cases

of pneumococcal meningitis which showed mononuclear infiltration. We might wake up some day suddenly to find that many things called syphilitic were not syphilitic.

Dr. Israel Strauss of New York said that he thought that what Dr. Southard had said was true. We found leucocytic infiltration in tuberculosis and in other conditions of the nervous system. It was the method by which the nervous system reacted to infectious states in the acute or subacute types. In the chronic states we did not know of anything in the present state of knowledge which gave the lymphocytic infiltration which syphilis did.

Dr. Collins of New York said he ventured to suggest that this paper that Dr. Spiller had presented was an extremely important one, and would mark a very distinctive period in the interpretation of spinal cord diseases. There could be no doubt that what Dr. Southard had said was true, but it did not invalidate the importance of Dr. Spiller's claim and contention. It would permit making an investigation of cases clinically, demonstrating a syphilitic disorder. For instance, we would not be justified in allowing any case of amyotrophic lateral sclerosis to go through our hands without repeated investigation as to whether or not the syphilitic poison existed in the system, and it seemed to Dr. Collins that that was the great application to our problem of the contribution that Dr. Spiller had made.

Dr. Spiller, in closing, said that he had not expected to have his views accepted in large part. It would not have been worth while to have presented the paper if he had expected that. He emphasized that he did not say that every case of amyotrophic lateral sclerosis or chronic bulbar palsy was syphilitic. He wished only to call attention to the possibility of syphilis occurring in a number of such cases and he felt justified in reporting the study.

Acute Infectious Transverse Myelitis Due to the Virus of Poliomyelitis with Complete Recovery.—Dr. B. Sachs of New York presented this communication which consisted of the report of a patient, 18 years old, who presented all the symptoms of a complete acute transverse myelitis. A number of unusual symptoms and the marked tendency to improvement early led to the suspicion that the case was clinically not unlike one of acute poliomyelitis anterior. This suspicion was confirmed by the strictest laboratory proof.

Dr. Theodore Diller of Pittsburg stated that he had seen astonishing recovery in one case of the Landry type in which there was complete paralysis of both arms and legs and in a second case in which there was a transverse myelitis of unknown origin which was not syphilitic in character. He referred to those two cases because they indicated that in the most desperate cases recovery would sometimes occur.

Dr. Graeme M. Hammond of New York said that in an epidemic which occured in Princeton University, 5 young men were taken ill within two or three days. Four of these were undoubtedly cases of poliomyelitis. The fifth one was a case of transverse myelitis. He had not recovered yet, but was recovering. It was a typical case of transverse myelitis occurring in poliomyelitis.

Motion Pictures of Nervous and Mental Diseases.—Dr. Theodore H. Weisenburg of Philadelphia presented this communication, stating that the use of moving pictures in medicine was of comparatively recent origin, but that their use for illustration of scientific subjects was slowly developing and teaching institutions were equipping themselves to utilize them. The pictures offered great advantages for teaching medical students as the teacher had at his command illustrations of certain diseases and the student paid more attention to what he saw illustrated in this manner than when seeing the patient. Also by the photographs it was possible to detect certain phenomena which could not be seen by the naked eye. It was his purpose to show everything that it was possible to show in the realm of nervous and mental symptomatology. It was interesting also that the cases of patients who had since died could be reported and their ailment shown as they suffered in life.

Neurological Economics.—Dr. Charles L. Dana of New York introduced this topic by saying that neurology was a very important branch of medicine and should have for its end not only the teaching of the individual but of the community. For the past year he had been chairman of a committee which had been organizing several subcommittees and which had done considerable work though not ready to report on this yet. Of the special activities in which he had been interested one had been that of expert testimony. A year ago this association passed a series of resolutions in which they tried to formulate certain rules regarding the conduct of experts and expressed hopes regarding the reforming of legal procedures. It was desired to establish a minimum neurological qualification for experts. It was desired to have the payment of experts made by or through the courts and it was desired to abolish the contingent fee. The movement initiated had made progress and should be continued.

Industrial Occupational Neuroses.—Dr. M. Allen Starr of New York presented this part of the symposium. He said there were many dangers from accident in mines from exposure to dust in various factories and from exposure to poisonous fumes. The subject of particular interest to the neurologist included the effects of poisoning by lead, phosphorus, mercury and arsenic. These poisons were employed in a large number of industries, there being 130 industries in which lead entered as a factor and in which workmen were exposed to lead poisoning. There were dangers of plumbism in the manufacture of pottery. In England this had led to the passage of laws for preventing the employment of women in this trade, reducing the percentage of lead in the glaze to 5 per cent. and enforcing methods of cleanliness and ventilation in factories. Dr. Starr favored the passage of laws by the various State Legislatures regulating industries, and believed there was need of education among operatives employed in dangerous trades. This education should be given by the employers by means of notices posted in factories and distributed among the employees and by means of instruction given by the labor union to their members. He also believed that if such information were given to manufacturers and if their attention were called to the importance of the health of their employees, many needed reforms would be voluntarily carried through by them.

Dr. Dana of New York said there were some particular things which the members as individuals might say in regard to the matter. They came in contact a great deal with occupation neuroses. For example, the occupation neuroses, such as the cramps, neuritis, neuralgias, made up about 1 per cent. of the material in his dispensary. It was along those lines that the members as neurologists could do a good deal of work. Then another thing that bore upon this question was the importance of domestic, social, and industrial conditions in connection with the development of psychoneuroses. By the help of social workers and by prying into the environmental and working conditions of the dispensary patients he found that the individual conditions were extraordinarily important in the development of these psychoneuroses.

Dr. Starr of New York said that if every man in the room would take the plans to have in his clinic a card catalogue by means of which every disease that was referable to an occupation should be tabulated, at the end of 2 to 5 years we would have a mass of statistics that would be of great interest and use to neurologists in working on this subject. Our information was indefinite at the present time.

Social Work in Connection with Neurological Dispensaries.—Dr. James J. Putnam of Boston presented this paper. He stated that the general object and character of the social service work at the Massachusetts General Hospital were now so well known that it was unnecessary to dwell upon that aspect of the subject. The plan had been, as regarded that part of the work which related to neurological cases, to spend a considerable amount of time over a small number of persons rather than a little time over a larger number. Two paid workers are now employed, one receiving $1,000, the other $720 a year. In addition, an expert psychologist has given a considerable part of his time to working among chosen cases and studying the mental condition of boys sent from the Juvenile Court. The work of this gentleman has been a valuable addition and he has been remunerated to a certain extent from a special fund. The department has no organic connection with the hospital, but it is hoped that the improvement in standards of work will eventually make itself felt even in the routine work of the hospital. Besides going about among patients and making friends with them, and studying the personal condition of their lives, this department has carried on an occupation class where girls and women are taught pottery work. In general terms it may be said that the chief element of success in the work has been the devotion and intelligence of the social workers.

Social Service and Social Research in Neurological Hospitals and Dispensaries.—Dr. Joseph Collins of New York read this paper. He said that the sick person who goes to a public hospital or dispensary should be so handled that this should not prove to be the first step toward loss of voluntary independence. There should be an actual inspection from a social standpoint of the attitude of each patient toward the payment of fees in order

that it shall not be easier for him to assume a more dependent attitude toward the institution than if he were a private patient, nor easier to cheat the dispensary by fraudulent representations than to cheat the private physician. This relation of the patient to the institution should be under continuous inspection during the entire time of his connection with it. In judging the results of the patient's contact with the institution a criterion should be established by which an estimate can be made of the adjustment of the individual to life in terms of occupation. The new social situation arising from the recognition of the residential status of the patient contains opportunities for social instruction that should be fully utilized. It is vitally important to know what effect the costly processes of curing disease are going to have on the future social relations of the individual. Science and common sense both agree that the individual must be defined in terms of his ability to put forth effort in economical ways toward well-chosen aims. A sound sociology on a sound psychological basis will insist upon studying an individual suffering from disease and resident in a hospital not only in terms of his native energy but of his natural or acquired tendencies in expanding them. When this observation is carried on in connection with actual occupation a situation is created which is favorable for educational purposes and which should be utilized through persuasion, argument, or actual demonstration.

Dr. Dana of New York said his experience has been that no neurological clinic was complete or could be really effective to do good work without having a social service connected with it. Everyone who had tried it would realize that fact. It was not always possible to have one.

Dr. Morton Prince of Boston said that a social service was one of the most important connected with the neurological clinic. After an experience of a great many years he had been impressed more and more with the necessity of some means of looking after the patient not only while he was in the hospital but after he left. A large proportion of the patients who come to the clinic were afflicted with functional disease of one kind or another, which came in a large extent from the inability of the patient to adapt himself to environment.

Retardation and Constitutional Inferiority in Connection with Education and Crime.—Dr. Hugh T. Patrick of Chicago presented this paper, which consisted of a narrative of the work of Dr. Healy, who had been working with old offenders in the Juvenile Courts of Chicago for about two years. His study of these criminals had been intensive. He goes as far as possible into the questions of heredity and environment, including social influences, family influences and everything else possible. He makes a examination and also to the extent of his ability and the time allowed a psychological examination. He has made a tentative classification based on 800 cases. The largest single causative factor of delinquency recognizable by study of the individual offenders is mental defect. They belong in the class of individuals concerning which society needs the assistance and advice of physicians. Society needs this advice while these offenders are young because a very potential factor in the criminal is the crime habit. It is a tremendous force in criminology and this develops young. One point which Dr. Healy showed in figures and in a perfectly definite way was that a good many of these cases were criminals; they were repeated and chronic offenders because the condition had not been recognized and consequently the child had not been properly directed. That this work of Dr. Healy's has been appreciated was shown by the fact that at the meeting of the Board in Dr. Patrick's office the judge of the Juvenile Court said that he did not know what he would do without Dr. Healy's assistance in his court as these questions are constantly coming up and he would not care to take the responsihility of deciding them. An effort was heing made to get a man to do similar work in the court for adult criminals and the money had been provided to pay for such work but they had been unable to find a man to undertake it. Dr. Healy also greatly desired an assistant.

Saturday, June 1—Third Day.

Presentation of Brain Specimens Exhibiting Lesions of Special Interest for Localization of Aphasic Disorders.—Dr. La Salle Archambault of Albany read this paper giving a practical demonstration of the lesions found in two cases carefully observed clinically. In the first case there was complete destruction of the posterior third of the left inferior frontal convolution in a right-handed subject who never presented any evidence of aphasia. In the second case an old apoplectic scar occupies the anterior portion of the left middle frontal convolution and a relatively recent hemorrhagic focus destroyed the posterior two-thirds of the left lenticular nucleus, but the left inferior frontal convolution was intact. The patient, who was right-handed, presented well marked, though not absolute, motor aphasia.

Epilepsy in the Adult.—Dr. Edward Fisher of New York read this paper, saying that for a long time he had been interested in epilepsy in the adult, especially senile epilepsy. Epilepsy frequently occurs in young adults without any previous history of seizures. In these cases there was no arteriosclerotic basis as there was in the central form. They differ also entirely from the class of epileptics which have their origin in early life. One of the principal causes of epilepsy in the young adult was syphilis. Not that we get necessarily all the symptoms of syphilitic endarteritis or of paresis, although at times there is a difficulty in making a differential diagnosis between these conditions and general paresis. He referred more to the type of young people of 20 to 25 who are actively engaged in college work or in some other form of excessive application in whom the special senses are called upon, especially where there is associated a great deal of anxiety. In the adult cases we do not notice the mental deterioration which is observed in childhood. They are as clear mentally after the attack and resume their vocation with the same mental grasp as before. They do not have either the facial appearance of the epileptic. Therefore, in getting at the pathology of these cases one should not look upon toxins or overstrain as the basic cause, but should regard these as an exciting cause. There must be some fundamental weakness or instability back of the condition. These cases were not easy to treat; they required rest, but did not respond to treatment better than the other forms of epilepsy.

Arteriosclerosis Probably Not an Important Factor in the Etiology or Prognosis of Involution Psychoses.—Dr. G. L. Walton of Boston read this paper. He stated that arteriosclerosis without gross cerebral lesion should not be too readily accepted as a cause of symptoms. The writer had examined with reference to clinical evidence of this condition 100 cases of marked involution psychosis, choosing the depressed phase of manic-depressive insanity commonly classed as involutional, often with agitation, with self-accusation and with somatic delusions. The same number of control cases have been studied for comparison. The result has shown no greater prevalence of palpable arteries, high blood pressure, apoplectiform attacks or other evidence of arteriosclerosis among the psychoses than among the control cases of the same age and condition. Until, therefore, definite evidence was forthcoming beyond the fact that post-mortem examination sometimes revealed cerebral arteriosclerosis, no reason appeared for assuming its presence, or for regarding it, when found, as other than a coincidence. Furthermore, so large a proportion of these cases fell in the chronic and hopeless class as to render it doubtful if arteriosclerosis should be regarded as having an important bearing on the prognosis.

The Neurological Disturbances of Alzheimer's Disease.—Dr. Albert M. Barrett of Ann Arbor presented this communication which consisted of the report of a woman at the age of 53 who developed a progressive spastic atrophic paralysis, involving the head, trunk and extremities. This was accompanied by profound mental deterioration. Death occurred after two years. The pathological findings were those of marked cerebral atrophy with secondary cord degenerations, the histological process in the brain being the intracellular neuro-fibril degenerations and plaque formation of Alzheimer's disease. The case was unique in the early age of occurrence of this disease and in the severity of the neurological disturbances.

Dr. Henry M. Cotton of Trenton said he considered Dr. Barrett's communication not only extremely interesting but extremely important from the standpoint of histology. It had been stated at this session that perhaps histology still had a place in psychiatry. Dr. Barrett's paper showed that it not only had a place, but a very important place. This disease of Alzheimer's was an important complex and this case was interesting because of the careful clinical analysis of the symptoms and the neurological examination showing not only the classical findings, but the cord degeneration as well. We should emphasize in a broader sense the progress of the pathological histology as shown by this case.

Dr. Collins of New York congratulated Dr. Barrett on the model way in which his case had been studied and reported. It was really a great pleasure to see a new member of the Society handle a subject in the masterly way in which this had been done by Dr. Barrett.

The Metastasis of Hypernephroma in the Nervous System; Jacksonian Epilepsy Caused by Such Lesion.—Dr. Joseph Collins and Dr. R. G. Armour of New York presented this communication which detailed the case of a man 45 years old who had been in good health and who

developed typical Jacksonian epilepsy, displaying itself by twitching of the left thumb and index finger, paresthesia of the left hand and forearm and followed on five occasions by loss of consciousness and generalized convulsions. Gradually there developed loss of power and of dexterity in the left upper extremity and to a slight degree in the entire left half of the body. The only definite physical signs were loss of sense of position in the left hand and fingers and absence of the left plantar reflex. There was an inconstant astereognosis of the left hand, and a mild increase of the tendon jerks of the left half of the body. A week before his death a slow rhythmical tremor of the left thumb and index finger consisting of adductor movements about one per second developed. When the abdominal cavity was opened a large whitish tumor was found in the right flank, invading the upper pole of the kidney and showing microscopically the structure of adrenal tissue. There was metastasis to various organs including the brain, but in the brain all trace of adrenal tissue was lost.

Case of Confusional Psychosis Following Hysterectomy.—Dr. Richard Dewey of Wauwatosa, Wis., read this paper which consisted of the history of a patient of 47, who after showing climatic changes and anemia, underwent curettage in August, 1909, when she was then found to have multiple uterine fibromyoma (which produced marked autosuggestion of cancer). September, 1909, vaginal hysterectomy. No postoperative physical complications but mental state abnormal. She refused food largely and after 14 days, totally. Mechanical feeding became necessary and had remained so for 2½ years. Delirium continuing at the hospital, she was transferred to a sanatorium 4 months after operation. At this time she was completely disoriented as to time and place, and had constant visual and auditory hallucinations and persecutory ideas. She had no control over her evacuations. Numerous brief periods of partial or complete lucidity ensued—the longest 3 hours. She had frequent motor agitation, but no voluntary or purposive movement. She would not walk or stand, though strong and well-nourished. Indicanuria was present at times. Lucid periods often complete as to memory and logical power. Voluntary attention extremely weak. Mental state (during lucid interval) seemed normal except for this and the natural inability to grasp present situation and the retention of persecutory ideas. The therapy had consisted in thyroid feeding, continuous baths and sleeping outdoors. The patient was still in *statu quo*, except that consciousness had widened somewhat.

Dr. F. W. Langdon of Cincinnati said that neurasthenics and psychasthenics were bad subjects and it would be better to postpone operations until the patient's resisting powers were on a higher plane or until they had passed through the impending crisis whether or not this was of an epochal character.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held at the Barnard Free Skin and Cancer Hospital, St. Louis, Missouri, May 23, 24, and 25, 1912.

The President, Dr. Grover W. Wende of Buffalo, in the Chair.

(Concluded from page 501.)

Pellagra.—Dr. Oliver S. Ormsby of Chicago presented sented an abstract of the work done by the Pellagra Commission appointed in 1909 by Governor Charles S. Deenen to investigate the disease as it was exhibited in the State of Illinois. As the result of the investigation of the commission the conclusion reached was that pellagra was a disease which appeared to be due to infection with some living microorganism, possibly of protozoan character. A possible habitat for this parasite in man was in the wall of the intestine. The most plausible view of the mode of entry into the body was by way of the blood stream. The part played by insects was conjectural. The number of cases of known pellagra rendered this disease a decided menace to the public health of the State of Illinois and it seemed important, therefore, that a careful search should be made for cases outside of the state hospitals and that physicians everywhere should be informed concerning the possible development of a disease that had been a national calamity in Italy for one hundred and fifty years.

Acanthosis Nigricans, with Report of a Case.—Dr. Alfred Schalek of Omaha reported this case in detail. The first description of the disease was made simultaneously and independently by Pollitzer and Janovsky in 1890. The disease was of special interest and importance on account of its almost constant association with malignant neoplasms. This complication was usually known at the time of or even before the skin manifestations, but in some instances there was no suspicion of its presence until a tentative diagnosis of the skin changes caused a successful search for it. The pathognomonic cutaneous symptoms, more or less always present, were widespread pigmentation, hypertrophy of the papillary layer of the skin, and hyperkeratosis of the horny layer. Less constant were affections of the mucous membranes and dystrophies of the appendages, the hair and nails.

Seborrhea Capitis.—Dr. George Thomas Jackson and Dr. Charles Wood McMurtry of New York stated that instead of one disease the seborrhea of Hebra, with its oily, dry, and inflammatory forms, we now had four diseases, namely, seborrhea, pityriasis simplex capitis, pityriasis steatodes, and seborrheal dermatitis. Seborrhea was distinguished by simple oiliness of the scalp, by the seborrheal filament, and by the presence of the microbacillus in large numbers on the scalp and in the hair follicles. Pityriasis simplex capitis was distinguished by dryness and excessive branny scaling of the scalp, absolute absence of inflammation, and the presence of immense numbers of the spores of Malasez. Pityriasis steatodes was distinguished by the presence of greasy scales on the scalp and hair, by the absence of all signs of inflammation, and by the presence of the polymorphous coccus with gray colonies. Dermatitis seborrhoica was distinguished by the presence of rather coarse, greasy scales and crusts upon a reddened and inflamed scalp, by its proneness to occur elsewhere than on the scalp, and by the presence of a mixed infection with the spores of Malasez, the polymorphous coccus with gray colonies, and the microbacillus.

Dr. Alexander S. Wolf of St. Louis emphasized the importance of instructing patients to take better care of their scalp from early childhood. It was his custom to impress upon his patients the importance of having an individual brush and comb and seeing that they were kept properly cleaned.

Dr. M. B. Hartzell of Philadelphia asked those members who took such elaborate care of their patients who were suffering from seborrhea of the scalp whether their successes were greater than those who merely advised the use of sulphur preparations, or whether they also failed to cure them.

Dr. George H. Fox of New York said that in these cases he had tried many of the parasitic preparations that had been so highly recommended, and his success with them had been no better than would result from a thorough washing of the scalp, together with remedies directed toward an improvement in the general health of the patient. Among the women who did not believe in frequent washing of the scalp would be found many with magnificent heads of hair, which apparently continued to grow in spite of the parasites that might be present. He believed that baldness, like the color of the hair, ran in certain families and that it was not preventable. The idea that it was due to using the same comb or brush seemed to him perfectly absurd, in view of our everyday experience.

Dr. E. S. Lain of Oklahoma City said he had been making a study of the skin lesions among the American Indians in Oklahoma, and had examined about 4,000 persons, many of them school children, in whom he made a particular note as to the presence or absence of seborrhea. Among the older Indians, who used their fingers or a thorn instead of a comb, seborrhea was practically unknown, while among the Indian school children, who were confined to the schools under strict regulations and were taught to use the common comb and brush, seborrhea of the scalp was present in from 65 to 75 per cent.

Dr. Pollitzer said that, so far as he knew, seborrhea was unknown among the lower animals and did not occur among savages generally. It belonged to civilized life. That seborrhea did not always produce baldness was of course well known. The deleterious effect on the hair and its vitality was due to the seborrheal organism. If there was a vigorous growth of hair this deleterious effect was not sufficient to destroy it; this was commonly the case in women and the same was true of the beard in man. These structures were secondary sexual characters, in the Darwinian sense, and possessed greater vitality than the hair on the head of a man, which was analogous in this respect to the vermiform appendix and of no great importance.

Dr. Jackson, in closing, said he had no doubt regarding the infectious nature of seborrhea, and that the proper care of the hair had much to do with its preservation. After the infection had once extended down to the hair follicles

a cure was difficult, if not impossible, and the best we could do was to keep the scalp in such a condition that when these parasites got on it they would have no chance to grow.

An Inquiry into the Efficiency of Sulphur Lotions.—Dr. O. H. Foerster of Milwaukee said that in sulphur we empirically recognized one of our most valuable dermatologic remedies for local use, but concerning its mode of action on the skin opinions to-day were still divided. It was certain that sulphur, as such, in contact with the skin remained practically inert, there being no interchange between sulphur and the keratin of the corneous layer, for both were insoluble. The action of the sulphur must consequently depend upon its conversion into a soluble form or gaseous product. Unna was the first to investigate this question and he concluded that sulphur acted by virtue of the hydrogen sulphide formed. His observations remained current and undisputed until Brisson, in 1909, asserted that the action of sulphur on the skin was due entirely to sulphuric acid formed by oxidation of sulphur. The efficiency of a sulphur preparation, according to Brisson, was therefore directly proportional to the amount of sulphuric acid formed from it by oxidation, while Unna and Golodetz considered its efficiency proportional to the formation of hydrogen sulphide. Further research was required for a definite decision of this question, though it appeared at present that Unna's conclusions were more securely founded. The watery suspensions of sulphur, as ordinarily prescribed and prepared, must be regarded as of little value, for sulphur was insoluble in water, and sulphur, as such, was practically inert. Measured by our theoretical standard, liquor calcis sulphurata was to be regarded as the most efficient sulphur lotion.

A Case of So-Called Prurigo Nodularis.—Dr. Joseph Zeisler of Chicago reported this case and showed the patient. He said the term prurigo nodularis had been selected by Hyde in the last edition of his treatise on skin diseases for a rather unique dermatosis which he described on the basis of but four observations, one of them his own. Of the others, one was published in 1880 by Hardaway in the Archives of Dermatology under the title "A Case of Multiple Tumors of the Skin Accompanied by Intense Pruritus." The other two cases formed the subject of a communication by Schamberg and Hirschler in the *Journal of Cutaneous Diseases*, April, 1906, under the heading "Two Cases of Multiple Tumors of the Skin in Negroes, Associated with Itching." There was a striking similarity in these four cases. All of them concerned women in middle life; in all the lesions varied in size from a small pea to a hazelnut; they were located chiefly on the extremities and gave rise to intense itching. Having once become established they showed little tendency to either further development or involution, and remained thus unchanged for years, uinfluenced by treatment.

Concerning Epithelioma of the Lip.—Dr. William Allen Pusey of Chicago, in this paper, limited himself to his own experience, giving the records of 44 cases of epithelioma of the lip seen in private practice and treated with the *x*-rays more than three years previous to January, 1912. In 40 of these cases, all men, the lesion was on the lower lip; four were on the upper lip; of these, three were women and one a man. The youngest patient was 28; the oldest, 90. The cases were for the most part selected cases, *i.e.* the lesions were as a rule superficial, not extending deep into the lip, but this statement by no means covered all of the cases, for some were not regarded as favorable and were treated only because an operation was not practicable. The list did not include many cases of extensive carcinoma of the neck following cancer of the lip. In only two cases were glands palpable at the time of beginning treatment, and of course, operation was urged in these cases. One of these was not helped, and presumably died of carcinoma, but the other had been well six years. In another case a gland developed beneath the angle of the jaw after the lesion on the lip had healed: the gland gradually subsided, and the patient, a physician, had been well seven and a half years. The lesions in these cases varied from small, finger-nail size nodular masses or ulcers with nodular borders and indurated bases up to ulcers covering nearly the entire lip or tumors the size of an olive. Of these 44 cases Dr. Pusey said he knew the subsequent history to January, 1912, of all but five, which he would be compelled to deduct from his list, together with one additional case, that patient having died from intestinal obstruction five months after an apparent cure of the lesion on the lip. Of the 38 cases whose subsequent histories were complete, 35 had an epithelioma of the lower lip; three of the upper. Twenty-eight of these patients were living and free from epithelioma of the lip or metastases arising therefrom in January, 1912. Four were well when last heard from, from three to seven years after their treatment. Four had died from other causes. Two were failures; the disease spread to the glands beneath the jaw and caused death. Two of the patients had lived nine years without a recurrence; seven had lived eight years or more; seven had lived seven years or more; five had lived six years or more; two had lived five years or more; five had lived four years or more and eight had lived three years or more. The mean average interval which had elapsed since treatment in the 36 cases was six years. Dr. Pusey said he was willing to treat any epithelioma of the skin with the *x*-rays, provided radical treatment did not require the removal of contiguous glands. After an experience of eleven years, and covering the treatment of several hundred epitheliomas with the *x*-rays, he felt more convinced than ever that, used with attention to technique and with proper regard to their therapeutic indications, the *x*-rays was one of the most useful, or the most useful, single agent of treatment in the service of dermatology.

Dr. George M. MacKee of New York said his experience in these cases was practically in accord with that of Dr. Pusey. With a more extended experience with this method of treatment he thought the limitations that had been drawn around the *x*-rays as a therapeutic measure were gradually growing less. He had learned a great deal in regard to postoperative *x*-ray work, particularly in the regions of the breast and neck, where the rays would control a certain percentage of inoperable cases of cancer, even when palpable glands were present.

Dr. Martin F. Engman of St. Louis said that cancer of the lip was a dangerous disease—the most dangerous of any place on the face—and he had always been under the impression that it was very risky to resort to the *x*-rays in a cancer in that region. Even in cases where the glands were not palpable and where the usual v-shaped incision was made by the surgeon, recurrences frequently took place under the jaw. While he did not wish to be understood as saying that a radical operation should be done in every case of cancer of the lip, yet theoretically it was indicated. We spoke of palpable glands, but that did not mean anything. In such a case you might find many involved glands upon proper exposure, being too small to be felt. There lay the danger. With the *x*-rays we could doubtless eradicate a cancer of the lip, but was it the best procedure?

Dr. L. Duncan Bulkley of New York said he had treated a large number of cases of epithelioma of the face, among them some with the *x*-rays, but not cases of epithelioma of the lip. In the *x*-rays we had an excellent method for treating lesions about the eyes and nose, but when the epithelioma was located on the lip he was inclined to agree with Dr. Engman that not only the cancer itself should be removed, but also the glands and connective tissue underneath the jaw.

Dr. Ormsby said that, while his results with the *x*-ray treatment were perhaps not as good as Dr. Pusey's, still he was a warm exponent of the treatment. He had been able to keep some of his patients under observation for years, and in addition to the excellent cosmetic results the cures had been permanent. The results in the cases of epithelioma of the lip were very satisfactory, and he felt that for epitheliomata of the skin radiotherapy was the preferable method of treatment, providing, of course, the proper technique was employed.

Dr. Pusey, in closing, emphasized the fact that he only recommended the treatment of epithelioma of the lip with the *x*-rays in selected cases, and then the selection should be made by an expert. Epithelioma of the lip should not be treated by anybody, whether by the *x*-rays or by surgical measures, unless the operator was an expert. He was simply advocating the proposition that in a considerable number of selected cases of epithelioma of the lower lip the *x*-ray was a perfectly eligible method of treatment, but it was a method which was liable to abuse if it was not carefully restricted to proper cases.

The Classification and Nomenclature of Cutaneous Syphilis.—Dr. George H. Fox of New York stated that in the diagnosis of syphilis the main point was to recognize the disease. The particular form or variety of eruption was of far less importance, but as this subsidiary diagnosis had often an important bearing upon the stage of the disease, upon the appropriate treatment, and upon the prognosis, it possessed value which was certainly worthy of recognition. Since we were all forced to classify in some manner, and to name the various forms of cutaneous syphilis, was it not possible for us to agree upon the best practical classification and to be in greater accord with one another in the use of names? To further such a desirable end was the aim of this paper. In describing the various syphilides most textbook writers,

even those with a large experience, were sadly hampered by what their predecessors had written. Their respect for authority and tradition was highly commendable, but it surely was unfortunate when it led them to a parrot-like repetition of terms and to the description of eruptions which they themselves had never seen. When we considered the common forms of syphilis, with which we were all so familiar, and omitted the rare, unique, and exceptional cases, seen scarcely once in a lifetime, did it not seem possible and practicable for the members of the American Dermatological Association to agree upon the use of certain terms, not only for our common convenience, but for the sake of our professional brethren who looked to us for guidance, and particularly that large class in which we were all interested—the future students of dermatology? Dr. Fox said that our present syphilitic nomenclature was both careless and confusing, and he emphasized the fact that a wide discrepancy existed between the commonly accepted description of many of the cutaneous manifestations of syphilis, as found in the textbooks, and their actual clinical appearance.

Dr. William Allen Pusey of Chicago said that absurdities in nomenclature were not confined to syphilis and skin diseases. Language was always in the making; names were given things upon the basis of associations that might become absurd to-morrow, and usage so established them that to undertake to change them would be fighting windmills. Dr. Pusey said he simply called attention to this aspect of the subject, although he was in favor of the suggestions made by Dr. Fox.

Dr. M. B. Hartzell of Philadelphia said that because a certain lesion was extremely rare it did not prove that it did not exist, and that was true of the vesicular syphiloderm. Therefore he thought it ought to be mentioned, rare as it was.

Dr. Joseph Zeisler was inclined to agree with Dr. Fox that the term vesicular syphilide might well be discarded. In his own experience of thirty years he had never seen it, and while vesicular lesions could doubtless occur in a syphilitic subject they were probably simply a coincidence.

Dr. James M. Winfield of Brooklyn said the term tubercular syphilide gave rise to a great deal of confusion in the mind of the student, who naturally associated the name with tuberculosis of the skin. Referring to the so-called vesicular syphilide, the speaker said he had never seen it.

The Dry Treatment of Certain Moist Dermatoses.—Dr. Charles J. White of Boston said the therapeutic ideas embodied in this paper were not wholly original, as their chief source of inspiration was derived from Dr. M. F. Engman of St. Louis, who advised the liberal use of cornstarch powder and the administration of quinine forced to its uttermost limits in the treatment of certain moist dermatoses. In some of the cases reported by Dr. White this advice was followed literally; in others the internal medication was dropped and the patients improved quite as rapidly without the unpleasant symptoms often associated with the forced ingestion of quinine. The details of the treatment were as follows: During the acute stages of the disease the patient was put to bed and kept there until all or practically all moist surfaces had ceased to appear. If there were many lesions upon the dorsal surface of the body an air mattress was supplied and kept well inflated. All natural functions were carried on in the reclining position, and the patient ate, slept, defecated, urinated, and rested in this recumbent position. The food was restricted to soft solids and the abundant ingestion of water; the air of the apartment was kept as fresh as possible; bathing was not allowed; sleep was encouraged; medicines were administered only when special general symptoms demanded them and the pith of the whole method lay in the external use of a bland, antiseptic, inexpensive powder pushed to its extreme limit. All these qualities were contained in borated talc, which was the material employed in these cases. The application of the powder was made through a sifter, and every lesion on the body was drenched with this powder as often as any moisture showed itself. If the diseases affected the scalp the hair should be sacrificed. The patient should lie naked in the bed and the sheet and blankets should be supported on a frame, so that nothing touched the body but the powder. Dr. White then reported in detail a number of severe cases of pemphigus and dermatitis exfoliativa in which this dry treatment was used with marked success. In three cases of pemphigus two were relieved or cured; one died from an intercurrent disease. In six cases of dermatitis exfoliativa all were relieved or cured. Under the older miscellaneous methods of treatment employed at the Massachusetts General Hospital in eight cases of pemphigus five died and three were relieved or cured. In fifteen cases of dermatitis exfoliativa ten died and five were relieved or cured. Upon comparison Dr. White said these figures spoke for themselves, and he expressed the hope that the dry method might be given a trial when the physician was confronted with the serious problem of caring for those afflicted with these serious and often fatal forms of moist dermatoses.

Dr. S. Pollitzer of New York thought the most essential element of this method of treatment lay in keeping the patient covered with powder, which cooled the skin and exerted a soothing influence on the nerve ends. It contracted the blood-vessels, and acted as a universal antiphlogistic application.

Dr. Martin F. Engman of St. Louis said that one objection to this method of treatment was that it rendered the patient very uncomfortable for the first week, on account of the dryness and cracking of the skin. This could be largely alleviated by giving these patients an occasional colloidal or starch bath, with the addition of a little bicarbonate of sodium. The bath could be repeated every day or every other day, and then, after the patients had patted themselves dry, the powder could be reapplied. The speaker said he was firmly convinced that the dry treatment gave excellent results in some of these cases.

Dr. O. H. Foerster of Milwaukee said he had used this method in a case of generalized exfoliative dermatitis. After the powder had been applied for a short time the patient was very uncomfortable, owing to the marked "splitting" of the skin. The treatment was persisted in for ten weeks, with complete recovery.

Dr. White, in closing, said that crusting in these cases must be guarded against because if one left even a single focus of pus in the body the patient would not get well until this focus was healed. The treatment must be thoroughly carried out in all its details, and this could best be done in a hospital. In his experience these patients were not rendered very uncomfortable by the treatment, and he was opposed to the use of any moisture on the body.

A Recurrent Eczematoid Affection of the Hands.—Dr. S. Pollitzer of New York said that for several years he had been observing a form of dermatitis which was not mentioned in the works on skin diseases and was generally confused with nummular eczema. Yet the disease presented certain features which served, in his opinion, to separate it sharply from eczema and place it, perhaps, in the group of the bullous diseases, making it possibly a form of dermatitis herpetiformis, but of a type so mild and uniform that it deserved special consideration. Briefly, the disease was characterized by the occurrence of pruritic groups of resistant vesicles which entirely and uniformly covered the surface of small, round, or elliptical areas on the back of the hands and the sides and back of the lower portion of the forearms. It remained stationary, without extension or confluence or change of outline for several weeks, and then the lesions dried up, desquamated, and disappeared, to be followed after varying intervals by repeated recurrences of similar character. During the eruption there was a moderate eosinophilia.

Speculations as to the Causation of Eczema.—Dr. James C. Johnston of New York discussed this phase of the subject, and concluded that by a process of exclusion the causation of eczema might be narrowed down to a derangement of the nitrogen metabolism, neither anaphylactic nor a defective synthesis of urea, but occurring where for the moment biochemistry could not demonstrate it. Color was lent to this theory by the appearance in its course of allergic phenomena and urinary evidence of deamidization. Perhaps the fault lay in a failure of protein-splitting in the intestinal wall or the blood stream before the tissues selected their store of amino acid nitrogen.

The External Origin of Eczema, Particularly the Occupational Eczemas, as Based on a Study of 4,142 Cases.—Dr. Frank C. Knowles of Philadelphia read this paper and offered the following conclusions: (1) Fully one-quarter of all cases of eczema were of definite external origin. Almost one-sixth of all cases of this affection were caused by the occupation of the individual. (2) Microorganisms were apparently not the cause of eczema, but probably played a secondary rôle in the affection. (3) The largest number of cases of the so-called occupation eczemas were seen in the workers in the household, and next most frequently in laborers. (4) Practically every occupation and every irritant exclusive of occupation might produce an eczema. (5) The portions of the skin exposed to the irritant determined the site of the outbreak. (6) The eruption not infrequently extended beyond the irritated areas, at times being noted on distant parts of the cutaneous surface. (7) The usual type of eruption noted was the vesicular or the squamous. (8) The eruptions noted in this paper had lasted for weeks, months, or

years, and showed a marked tendency to relapse. (9) It was rather hard to explain the susceptibility of some individuals to certain irritants, while others were not affected, excepting on the theory of a personal idiosyncrasy, an anaphylactic tendency causing sensitization of the skin. (10) As dermatitis and eczema of external origin had the the same clinical and microscopical picture, they should be classed under the heading of dermatitis.

Dr. ZEISLER said that, after listening to these papers, he felt like presenting the etiology of eczema in a rather paradoxical vein, something like this: when we had a case of eczema of which we knew the cause, then it was not eczema; and when we had a case of dermatitis and did not know the cause, then it was eczema. After all, we were forced to agree with the sentiment voiced by Walker that in eczema we were confronted by a disease regarding whose etiology we were absolutely ignorant.

Dr. HARTZELL said that during the past century we had not learned a single fact bearing upon the internal cause of eczema, while, on the other hand, we had learned much about the external causes. He did not wish to be understood as denying the possible origin of this disease; on the contrary, there were certain cases which he thought were of internal origin, because we could exclude external causes, but what the internal factors were he did not know.

Dr. GEORGE T. JACKSON said that in teaching this subject he was accustomed to tell his students that eczema was due to an unknown internal cause plus an external irritant. Most of the so-called trade eczemas were dermatitides; many eczemas, however, were due to some unknown, internal cause, and he had seen cases of what he would term purely nervous eczema.

Dr. RAVOGLI said he had always insisted upon drawing a sharp line between dermatitis and eczema. He regarded a dermatitis as an acute affection, and that eczema began when the dermatitis ceased to be acute.

Dr. GRINDON said he regarded eczema as a peculiar type of inflammation, due to a wide variety of causes and analogous to catarrh of mucous membranes. He did not believe that these eruptions were due solely to an external irritant, because the fact remained that such an external irritant would not produce a lesion in everybody, for the reason that everybody's skin was not sensitized to it. One might handle formalin, for example, for a long time before the skin became sensitized.

Dr. ALFRED SCHALEK of Omaha said we might continue to discuss interminably whether the causes of eczema were internal or external, but the fact remained that whatever the causative factors were they were more or less present universally. In spite of this the majority of people escaped eczema, so that the conclusion was forced upon us that eczematous individuals must have a special vulnerability of the skin which unquestionably was in many cases inherited.

Dr. O. H. FOERSTER of Milwaukee said he was firmly convinced that many cases of so-called eczema were really due to external irritants, regarding the nature of which we were still ignorant.

Dr. HOWARD MORROW of San Francisco said that during the past year he had seen two cases of recurrent eczema developing after burns.

Dr. E. WOOD RUGGLES of Rochester, N. Y., mentioned a dermatitis connected with the photographic industry and due to platinum poisoning.

Report of Four Cases of Keratosis Follicularis (Darier's Disease).—Dr. W. H. MOOK of St. Louis reported these cases in detail and said that the unusual experience of treating three typical cases of keratosis follicularis in the St. Louis Skin and Cancer Hospital at the same time, and a fourth in the private practice of Dr. Martin F. Engman a short time previously, suggested to him that perhaps this disease was not as rare as had been claimed by the various writers on the subject.

Can Psoriasis Be Cured?—Dr. A. RAVOGLI of Cincinnati read a paper on this subject. He said it was unfortunate that so far we had not come to an understanding regarding the nature of the trouble, and that when we were able to establish the cause of psoriasis we would perhaps be able to treat the disease rationally. With the local application of chrysarobin and other irritating remedies the eruption usually disappeared, but only temporarily, and the irritation produced by these applications often gave rise to a dermatitis, in some cases followed by the recurrence of the psoriatic patches much larger and deeper than before. The same was true after *x*-ray exposure; the drying up of the epithelial elements caused temporary improvement, which was usually followed by the appearance of more stubborn lesions. Personally, Dr. Ravogli said, he had practically abandoned the use of chrysarobin, pyrogallol, or tar in these cases, for the reason that they caused too much discomfort to the patient, and he found that in ordinary psoriasis a white precipitate salve gave the best results. He also employed, with good results, subcutaneous injections of a 10 per cent. solution of cacodylic acid, repeating the injection two or three times a week. When the internal use of arsenic had no more effect in psoriasis he turned to potassium iodide. In many cases which had been treated for years with arsenic preparations, chrysarobin, etc., he had obtained brilliant results by giving potassium iodide internally and applying the white precipitate salve locally. Many of his psoriatic patients treated with these remedies had shown no recurrence for years, and had given him the idea that psoriasis was curable.

Granuloma Inguinale Tropicum; Report of Three Cases.—Dr. JOSEPH GRINDON of St. Louis reported three cases of this affection and offered the following conclusions: (1) The disease was a rare one in this country. (2) It was characterized by a striking conformity to type. (3) The adjective *tropicum*, as a part of the title of this disease, was not wholly justified. (4) The disease in this country was not mainly one of women, as Manson said was the case in the tropics. (5) The negro race was especially liable. (6) The question of contagion must remain open for the present. (7) The peculiar bodies described by Donovan and Carter were not constantly present in this disease. (8) Spirochetæ were not constantly present.

Report of a Case of Multiple Lymphoid Tumors of the Skin.—By Dr. JAMES M. WINFIELD of Brooklyn.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CHRIST AMONG THE CATTLE. By FREDERIC ROWLAND MARVIN. Sixth Edition. 58 pages; cloth; price 50 cents. Sherman, French & Company, Publishers, Boston.

MANUEL PRATIQUE DE KINESITHÉRAPIE. By E. ZANDER. 188 pages; paper; illustrated; price 3 francs. Librairie Felix Alcan, Publishers, Paris.

FEVER NURSING. 7th Edition. By J. C. WILSON, A.M., M.D. 259 pages; illustrated; cloth; price $1.00. J. B. Lippincott Company, Publishers, Philadelphia.

A SYSTEM OF TREATMENT. Edited by ARTHUR LATHAM, M.A., M.D., F.R.C.P., and T. CRISP ENGLISH, M.B., B.S., F.R.C.S. Vol. I. GENERAL MEDICINE AND SURGERY. 1352 pages; illustrated; cloth. Vol. II. GENERAL MEDICINE AND SURGERY. 1335 pages; illustrated; cloth. Vol. III. SPECIAL SUBJECTS. 1194 pages; illustrated; cloth. Vol. IV. OBSTETRICS AND GYNECOLOGY. 883 pages; illustrated; cloth. Price $24.00 net. The Macmillan Company, Publishers, New York.

THE SURGICAL CLINICS OF JOHN B. MURPHY, M.D., AT MERCY HOSPITAL, CHICAGO. Vol. I, No. 2, April, 1912. 157 pages; illustrated; paper; price per year $8.00. W. B. Saunders Company, Publishers, Philadelphia and London.

THE SURGICAL CLINICS OF JOHN B. MURPHY, M.D., AT MERCY HOSPITAL, CHICAGO. Vol. I, No. 3, June, 1912. 174 pages; illustrated; paper; price per year $8.00. W. B. Saunders Company, Publishers, Philadelphia and London.

DIGEST OF COMMENTS ON THE PHARMACOPŒIA OF THE UNITED STATES OF AMERICA (Eighth Decennial Revision) AND ON THE NATIONAL FORMULARY (Third Edition). For the Calendar Year Ending December 31, 1910. By MURRAY GALT MOTTER and MARTIN I. WILBER. 784 pages; paper. Public Health and Marine Hospital Service of the United States, Publishers, Washington.

MONOGRAPHS OF THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. No. 4. A Clinical Study of Acute Poliomyelitis. By FRANCIS W. PEABODY, M.D., GEORGE DRAPER, M.D., and A. R. DOCHEZ, M.D. 187 pages; illustrated; paper. The Rockefeller Institute for Medical Research, Publishers, New York.

ARCHIVOS BRASILEIROS DE MEDICINA. Second Year. No. 1. By Prof. JULIANO MOREIRA and Prof. A. AUSTREGESILO. 166 pages; illustrated; paper.

ARCHIVOS BRASILEIROS DE MEDICINA. Second Year. Supplement to No. 1. By Prof. JULIANO MOREIRA and Prof. A. AUSTREGESILO. 95 pages; illustrated; paper.

BLOOD PRESSURE TECHNIQUE SIMPLIFIED. By W. H. COWING, M.D. 122 pages; cloth. Taylor Instrument Companies, Publishers, Rochester, N. Y.

Medicolegal Notes.

Evidence of Employment of Physician by County—Physician Cannot Delegate Duties Under Contract.—A physician who had treated members of a poor family unable to pay for further treatment, informed the town member of the board of supervisors, who told him to continue the treatment, and the supervisor would present the physician's bill to the board. The treatment was continued. The town board of health moved to certify the bill to the board of supervisors, which refused payment. This was held to sufficiently show that the person treated was an indigent person. Whether she was or not, the physician was legally employed, and entitled to recover from the county.

It was also held that a physician who has a contract with a health board to treat certain poor persons cannot hire another physician to do the actual work, and then collect from the county for such other physician's services. But where the contracting physician has furnished medicines of an unusual character for an unusual disease, he is entitled to recover therefor, though they were administered by another physician employed by him, who performed the actual treatment.—Chapman v. Board of Supervisors, Michigan Supreme Court, 134 N. W. 1025.

Osteopaths — Licensing — "Practice of Medicine" — Scientific Training—Single Treatment.—A defendant held upon an information charging him with practising medicine for money by treating a named patient for hay fever by osteopathy, without having registered his authority, as required by the Texas statute of 1907, Chap. 123, denied the constitutionality of the act. The United States Supreme Court (Mr. Justice Holmes giving the opinion) upholds its constitutionality. The act requires all unlicensed practitioners to prove their diplomas or exemption, and receive a verification license. Other applicants must pass an examination conditioned, among other things, on their being graduates of "bona fide reputable medical schools." The examinations are to be fair to every school of medicine, without discrimination against any particular system, and the act does not apply to dentists, nurses, masseurs or to United States army and navy surgeons, etc., in the performance of their duties. A person practising medicine within the meaning of the act includes, by section 13, one who treats or offers to treat any mental or physical disease or disorder, or physical deformity or injury, by any system or method, or to effect cures thereof and charge therefor.

Before the passing of the act the defendant had a remunerative practice as an osteopathist. He held a diploma from a chartered school of osteopathy, but it did not appear that he presented this diploma to the board of medical examiners, or attempted to secure a verification license or a license in any form. The board, in passing upon qualifications, does not examine in therapeutics or materia medica, which are not mentioned in the act. On these facts the Supreme Court was of opinion that the defendant had failed to show that the statute inflicted any wrong upon him, contrary to the fourteenth amendment. The court did not consider the definition of practising medicine contained in section 13 of the act as arbitrary or irrational, as contended by the defendant, and followed the Texas court in holding that the defendant was included therein. It presumed, until the Texas court should say otherwise, that the defendant's diploma would not be rejected merely because it came from a school of ostoepathy. Whatever may be the osteopathic dislike of medicines, neither the school nor the defendant suffers a constitutional wrong if his place of tuition is called by the act a medical school for the purpose of showing that it satisfies the statutory requirements. An osteopath professes to help certain ailments by scientific manipulation affecting the nerve centers. It is intelligible, therefore, that the state should require of him a scientific training. He, like others, must begin by a diagnosis. It is no answer to say that in many instances the diagnosis is easy—that a man knows when he has a cold or a toothache. For a general practise science is needed. An osteopath undertakes to be something more than a nurse or a masseur, and the difference rests precisely in a claim to greater science, which the state requires him to prove. The same considerations that justify including him justify excluding the lower grades from the law. It was no answer to say that the defendant was prosecuted for a single case. If the legislature could prohibit a general practice for money except on the condition stated, it could attach the same conditions to a single transaction of a kind not likely to occur otherwise than as an instance of a general practice. The distinction between gratuitous and paid-for services did not render the act invalid. This was sustained in the case of a Maryland statute in Watson v. Maryland, 218 U. S. 173, 30 Supreme Court, 644. Nor was the law made invalid as against the defendant by the fact that he had an established business when the act was passed. Collins v. State of Texas, 32 Supreme Court, 286.

Medical Expert May Base His Opinion of Skill Upon Results of the Treatment.—Action was brought for damages for the alleged negligent and unskillful treatment of a Colle's fracture of the tip of the radius and the ligaments of the wrist joint. This fracture was an aggravated one. The defendant diagnosed the case correctly, and treated the injured wrist by the application of splints and bandages, with the object of effecting a reduction of the fracture and a union of the bones. About six weeks after the accident the defendant determined that a union had taken place, removed the splints and bandages, and ceased treating the plaintiff. At the time of the trial the hand was in an abnormal, deformed position, the plaintiff had little or no use of the hand or fingers, and continued to suffer pain

The result, whether of the fracture, or of the treatment, was admitted, by the defendant, to be bad. The evidence of negligence or unskillfulness was the tesimony of experts, based wholly on the result. The negligence of a physician or surgeon cannot be inferred from a poor result alone. There must be evidence from expert witnesses tending to show improper or unskillful treatment, in order to sustain a charge of malpractice against the physician. But an expert witness may base his opinion that the treatment was improper wholly on the result, and such an opinion is evidence on which the court or jury may find negligence. The inference of negligence, in such a case, is not drawn from the result, but from the evidence of the experts.—Sawyer v. Berthold, Minnesota Supreme Court, 134 N. W. 120.

Undue Discrimination Against Expert Evidence in Charge of Jury.—In an insurance case the jury were instructed by the trial judge that it should consider the medical expert testimony which had been introduced as to the result of an autopsy, etc., with great caution; that they should make a painstaking investigation of all the facts, to reach the truth, and must not be confused or misled by such testimony, because while such testimony is sometimes the only means or the best way to reach the truth, yet it is largely a field of speculation, beset with pitfalls and uncertainties, and requires patient and intelligent investigation. On appeal the Tennessee Supreme Court held this instruction to be erroneous, as discriminating too strongly against such evidence. It was, moreover, error to warn the jury that they must not be misled or confused by expert evidence.

In regard to hypothetical questions, an instruction that the jury, in weighing the answers of medical experts to hypothetical questions, must look into all the evidence, and determine whether the facts supposed to exist in the questions asked did actually exist, because, if one fact supposed to be true included in hypothetical questions is really untrue (*i. e.* not supported by the evidence) then the opinion of the expert would be valueless, was held to be proper.—Fisher v. Travelers' Ins. Co., 138 S. W., 316.

Practising Without a License for Jury Where Evidence Does Not Conclusively Show Guilt.—In a trial for practising medicine without a license the testimony of the defendant, when examined as a witness in his own behalf, tended to show that he had not treated or offered to treat any disease of any human being in any way whatever "but that he merely made his medicine or tea from roots and herbs gathered from woods near by, and sold to people who came to his tent for it." As the evidence as a whole did not show guilt it was held that an affirmative charge in favor of the state should not have been given, the question of guilt being then for the jury.—Carter v. State, Alabama Court of Appeals, 57 So., 1022.

Is Chronic Appendicitis an "Illness"?—An application for an accident insurance policy warranted that the applicant had never received indemnity for any accident or "illness" except for a broken ankle. He had, in reality, been operated upon for chronic appendicitis, and had received from another company an indemnity for the time he was away from business on that account. "Illness" has been judicially defined in connection with insurance, as "a disease or ailment of such a character as to affect the general soundness and healthfulness of the system seriously and not the mere temporary indisposition which does not tend to undermine or weaken the constitution of the insured." It was held that the question whether the operation for chronic disposition was an illness falling within this definition was one for the jury.—Miller v. Maryland Casualty Co., C. C. Q., 193 Fed., 343.

Miscellany.

INDIVIDUALISM AND SOCIALISM IN MEDICAL ECONOMICS.

In the latter-day discussions regarding the relationship of the medical profession to the public, there are discernible two contrasting attitudes. In one of these the practitioner is urged to break away from the traditional self-immolation which has been associated with the peculiar humanitarian aspect of his vocation, and to adopt the methods of the modern business man in exacting an adequate fee from those who are able to pay it. This attitude also protests strenuously against the encroachment of public authorities on the domains that should rightly belong to the general practitioner, the over-ambitious exertions of health boards, and the nationalization of contract practice. The protest against the last tendency is seen to-day in the refusal on the part of the organized profession of Great Britain to have anything to do with the new scheme of national insurance, except upon terms that are satisfactory to the practitioners. The other attitude would place all medical practice under the direct control of the government and by eliminating the competitive business aspects of the practice of medicine, would virtually make all physicians employees of the State. The two opposing methods of attacking the economic problems associated with the healing art may be characterized as the individualistic and the socialistic conceptions. The individualist protests against the exploitation of the physician's skill by the general public; the socialist would appropriate by the right of eminent domain the talents of the medical profession. In the two articles abstracted below there are presented the main arguments of the opposing schools of "medical economists."

The Integration of the Medical Profession.—W. F. Campbell states that "social unrest, agitation, and dissatisfaction are the 'growing pains' of the body politic." The criticism of abuses in the medical profession is a sign of progress. These abuses are the secret division of fees; lodge practice; contract practice; and health board, hospital, and dispensary abuses. These are due to structural weaknesses in the profession itself. The vaunted altruism of the physician's calling has been overdone and has pauperized both the community and the profession. The latter itself must be solvent before it can with honor dispense its charities. The medical profession can correct its own abuses. If abuses exist in a dispensary they can be ended if the physicians refuse to attend this dispensary. The term "medical ethics" has provided a phantom bulwark behind which just issues are often evaded. "Medical ethics is only the golden rule crystallized into professional conduct. It does not imply self-immolation, emasculation, or the dethronement of professional dignity." The solution of the economic problems of the medical profession require an efficient organization, whose primary object should be the study of these problems. E. Elliot Harris of New York has promulgated a plan of organization which will be tried out in selected districts, and which if it meets with favor will be extended throughout the State of New York. In this plan it is proposed to establish a society of duly licensed physicians without regard to their designated school of practice, to be known as "The United Medical Societies of the State of New York." The purposes of this society as defined by Dr. Harris are: "(1) The enlightenment and direction of public opinion in regard to all economic matters in which the medical profession is concerned. (2) The maintenance of a high, uniform standard of medical education for all licensed physicians, for the protection of the public health, and for the proper care of the sick and injured. (3) The betterment of the economic conditions of the practising physician. (4) To assist in the enactment and enforcement of the medical and pure food laws. (5) The furtherance of the economic interests of the medical profession of the United States by friendly cooperation between the States." The plan of organization contemplates the establishment of local societies representing senatorial districts, the local societies sending delegates to the general assembly. There will be a central office in New York City in charge of a salaried executive officer whose duty it will be to visit and organize local societies, receive reports, and take under advisement the various medico-economic problems which confront the local societies.—*Long Island Medical Journal*, July, 1912.

What Is the Matter with the Medical Profession?—J. P. Warbasse makes a plea for the nationalization of medical practice on a socialistic basis. He finds that the chief trouble with the medical profession is that the doctor is a private tradesman engaged in a competitive business for profit. Just as the schools, the highways, the water supply, etc., have been removed from the hands of competitive business, so the public health should be organized throughout as a public service. The criminal and the pauper now receive the attention of the State. Why should not this attention be accorded also to the sick man? The latter is a social problem, and should not be left to the mercy of the business methods in medical practice. These methods are steadily on the increase, corresponding to the increasing pinch of economic necessity. "The doctor has his talent to sell. He is in the market. The competition is fierce. Most doctors are capable and able to deliver the goods. But comparatively rarely can they afford to give the time to do the best possible thing for the patient. . . . The general practitioner who neglects the methods of the tradesman, even though he gives to his patients the benefit of surpassing skill and knowledge, is apt to languish for a clientèle. He is surrounded by the competitive system, and unless he conforms to the methods of the warfare about him he must go down." The author cites the example of the Medical Corps of the Army and Navy, in which a high standard of efficiency is maintained. "Soldiers receive the best medical attention, not as a charity, but as a right." On the other hand, the workers who do the work of the world, are called "hands," and are "consumed as so much raw material to be fed to the flames of commerce." The reason for the difference of attitude of the nation toward the soldier and the worker is that the latter has "only just emerged from serfdom, while the soldier has behind him the prestige of many thousand years of fatuous superiority." Quackery is one of the results of the competitive system in medical practice. Moreover, the doctor who is engaged in the competitive struggle for a livelihood is least apt to contribute to the progress of science. Human life and happiness should be objects of solicitude on the part of the State, in whose employ the medical profession should be enlisted "as the great conserver of

the most precious of the nation's natural resources."—*Long Island Medical Journal*, July, 1912.

The Young Physician.—The "Night Call" is the title of a charming bit of fiction by Henry Van Dyke. The chief feature of this story is the pen picture of the young country practitioner, Leroy Carmichael, who came back to his home town to practise medicine after a thorough preparation in a medical school and hospital. He "arrived well accredited, and was received in his first year with many tokens of hospitality in the shape of tea parties and suppers. But the final and esoteric approval of Calvinton was a thing apart from the mere fashionable courtesies and worldly amenities, a thing not to be bestowed without due consideration and satisfactory reasons. Leroy Carmichael failed, somehow or other, to come up to the requirements for a leading physician in such a conservative community. He was brilliant, perhaps, a clever young man; but he lacked poise and gravity. He walked too lightly along the streets, swinging his stick, and greeting his acquaintances blithely, as if he were rather glad to be alive. Now this is a sentiment which Calvinton regards as near akin to vanity, and, therefore, to be discountenanced in your neighbor and concealed in yourself. How can a man be glad that he is alive, and frankly show it, without a touch of conceit and a reprehensible forgetfulness of the presence of original sin even in the best families? The manners of a professional man, above all, should at once express and impose humility. Young Dr. Carmichael had been spoiled by his life in New York. It had made him too gay, light-hearted, almost frivolous. It was possible he might know a good deal about medicine, though doubtless that had been exaggerated; but it was certain that his temperament needed chastening before he could win the kind of confidence that Calvinton had given to the venerable Dr. Coffin, whose face was like a tombstone and whose practice rested upon the two pillars of podophyllin and predestination."

The same story contains another excellent example of the author's knowledge of medicine and of the wonderful gift of word-portraiture in his description of an attack of angina pectoris. The patient, a woman past middle age, is telling the doctor about her sudden illness during the night. "'It was the first time—like a flash of lightning—an ice-cold flame of pain—.' Even as she spoke a swift and dreadful change passed over her face. Her color vanished in a morbid pallor; a cold sweat lay like death-dew on her forehead; her eyes were fixed on some impending horror; her lips, blue and rigid, were strained with an unspeakable, intolerable anguish. Her left arm stiffened as if it were gripped in a vise of pain. Her right hand fluttered over her heart, plucking at an unseen weight. It seemed as if an invisible, silent death wind were quenching the flame of her life. It flickered in an agony of strangulation."—*Harper's Magazine*, August, 1912.

Heine and Homeopathy.—The following anecdote of the German poet is related in Ughettis' "With Physicians and Clients": Returning from a journey to the south of France, Heinrich Heine met a friend, a German violinist, in Lyons, who gave him a large sausage that had been made in Lyons with the request to deliver it to a mutual acquaintance, a homeopathic physician, in Paris. Heine promised to attend to the commission and intrusted the delicacy to the care of his wife, who was traveling with him. But as the postchaise was very slow and he soon became very hungry, on the advice of his wife both tasted of the sausage, which dwindled with every mile. Arriving at Paris, Heine did not dare to send the remainder to the physician, and yet he wished to keep his promise. So he cut off the thinnest possible slice with his razor, wrapped it in a sheet of vellum paper and inclosed it in an envelope, with the following note: "Dear Doctor—From your scientific investigations we learn that the millionth part of a certain substance brings about the greatest results. I beg, therefore, your kind acceptance of the accompanying millionth part of a Lyons sausage, which our friend gave me to deliver to you. If homeopathy is a truth, then this little piece will have the same effect on you as the whole sausage. Your Heinrich Heine."—*Medical Review of Reviews*, August, 1912.

Physical Examination of Motorists.—F. M. Bogan states that in Germany legislation provides for the physical examination of persons applying for motor licenses. This examination is much more rigid than might be expected. Of course, nearly normal vision and hearing are required. Those having squinting or astigmatic eyes, the color blind, and the night blind are rejected. In the case of hearing, the whispered voice must be heard at nine feet. Especial attention is paid to the detection of those suffering from neurasthenia, giddiness, or insanity—these of course being barred. The arm and the leg most used in operating a machine must be normal, and in case the applicant has lost one or more fingers, or has deformities of the hand, he is given an opportunity to demonstrate his fitness or unfitness for driving a car. The provisions of this examination are so eminently sound and practical that the general adoption of regulations along the same lines would, in the author's opinion, very greatly reduce the excessive number of automobile accidents in this country.—*Lippincott's Magazine*, September, 1912.

In the Tool-Box of the Automobile.—Besides the special tools given with each make of car, and usually adapted especially to its particular parts, there are always a few handy things of general usefulness which the motorist can with profit carry. A small pocket electric torch is extremely convenient, for examining the amount of "gas" in the tank at night, for instance, and can be bought for a dollar or less. A small monkey wrench, such as is made for use on bicycles, is often convenient, as it is but half as thick in the jaws as the regular style, and will fit some places which would otherwise take only a thin "spanner." A small funnel, probably of copper, tinned inside, is useful for filling the oil tank. With the equipment of the car comes usually an oil can which is often too large for ordinary use. For "touching up" such places as the spark and throttle levers and oil holes in various places a small oiler such as is used for sewing machines and other light machinery will be found of considerable value. Special benzine cans, approved by the boards of fire underwriters, are sold for the use of tailors, printers, etc. The one-pint size to carry gasoline for cleaning hands, spark-plugs, and anything else will be found of the greatest convenience. It is safe as regards the risks usually incident to gasoline and is most readily accessible. No one who has once carried this accessory will ever dispense with it.

THE UNJUSTIFIED PREJUDICE OF TUBERCULOUS PATIENTS AGAINST SANATORIA AND HOSPITALS.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY OF THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, NEW YORK.

ANY physician, be he general practitioner or consultant, who has to deal with tuberculous patients and who considers sanatorium treatment to be indicated in many cases, will be confronted frequently, perhaps in the majority of the cases which come under his observation, with a type of fear or preconceived dislike for institutional treatment, which for lack of a better name we may call sanatoriumphobia or hospitalphobia. This fear of institutional treatment amounts, in some individuals, to a veritable horror. The first thought with which this sanatoriumphobic individual is possessed is the idea that he is sure to meet patients much sicker than he himself who are real consumptives, while he imagines himself to be only slightly tuberculous. Perhaps it is only in the presence of the physician who diagnosed his case that he is willing even to admit that he may be tuberculous. This peculiar state of mind which consists in not wishing to be classified with other tuberculous patients or only with those having weak lungs, is pardonable although characteristic.

It seems that a typical tuberculous patient does not like anything better than to find some physician who, in spite of the positive diagnosis of several others, confirmed by positive sputum tests, will declare that he only has weak lungs. I remember a case referred to me by a most excellent diagnostician for confirmation of diagnosis and advice for treatment. The patient, a few weeks before, had had a profuse hemoptysis. There was not the slightest doubt as to a positive diagnosis. I made arrangements for his reception in a sanatorium, and the young man, who was engaged to be married, promised me faithfully to remain in the sanatorium at least one year, and only to think of marrying after his case would have been declared to be absolutely arrested. Imagine my surprise when, two weeks later, the sanatorium physician sent me a letter which the patient had written him wherein the family physician, another consultant, and myself were denounced in no gentle terms and the arrangements for sanatorium accommodation cancelled; and all this because a life insurance examiner had declared the young man sound and well and had accepted him at a very low risk.

When the patient's fear of reinfection is argued out of him, when he is told that the well equipped sanatorium is the safest place not to contract the disease, that the precautions there preclude a possibility of becoming reinfected, he will bring forth another excuse for not wanting to go to a sanatorium. He will say that he is unable to bear the sight of other patients more ill than himself; he will fear the depressing influence of constant coughing and perhaps even of seeing a patient hopelessly ill or in a dying condition. When the physician will have assured him that there is less coughing in a sanatorium than there is during a grippe epidemic in any street car of an average sized city; that if there are any patients more ill than he, he will not see them; that the sanatorium has only relatively early cases; that the spirit, the mental atmosphere of the sanatorium is one of hope, contentment, and even gayety, the prospective sanatorium candidate will bring forth a third excuse. He will say, "But, Doctor, I shall be stigmatized. If it becomes known that I am tuberculous and an ex-patient of a sanatorium, I will be ostracized. My former employers will not wish to take me back into their office or shop." That there is some justification in this excuse for sanatoriumphobia we must admit, for here we approach the subject of phthisiophobia, which, alas, is still rampant in some sections of the country and among some people who have not informed themselves of the fact that the honest, conscientious consumptive, particularly the one trained in the sanatorium, is not a menace to his fellow-men, and that to the arrested or cured case with absolute freedom from bacilli all avenues to work and society should be open.

The object of my paper to-day, my reason for publishing it, giving it as wide a circulation as possible, and placing it in the hands of sanatorium physicians and others interested in the cause, is to remove this unjustified fear of tuberculous patients who have to enter the sanatorium. I should like to convince the patient that he need not fear being ostracized if he will but do his duty. I cherish also the hope that this modest effort on my part, but above all the valuable contributions to my plea which have come to me from leading sanatorium directors, will convince employers and others that phthisiophobia is unjustifiable and that to exclude the cured and thoroughly arrested case from any employment is cruel, unjust, and inhumane.

Last, but not least, I trust that after reading this little contribution, prospective patients will see that their fears of becoming infected or reinfected in a sanatorium are totally unjustified; that life in a sanatorium is far from depressing; that on the contrary, an atmosphere of hope, cheer, and good comradeship prevails in sanatoria; and that they themselves can contribute to this in no small degree by determining to get well, obeying implicitly the rules of the institution, being of a hopeful and cheerful frame of mind, sympathetic and kind to their fellow patients.

*Read before the Sociological Section of the National Association for the Study and Prevention of Tuberculosis, at its annual meeting in Washington, May 30, 1912.

To have the statements I am going to make as authoritative as possible, I addressed the following questions to a large number of physicians at the head of American and Canadian sanatoria: Has there ever been an authentic case in your institution of a healthy visitor or employee (physician, nurse, or helper) having contracted tuberculosis during his sojourn in the sanatorium, and if so, how many cases have you on record, and covering what period of time? Have you observed among the patients who have come to the sanatorium any who have left the institution shortly after their arrival because they found the association with other patients unpleasant? Do you know of any patients who have suffered from social or business ostracism after having left your sanatorium, either cured or arrested?

With a courtesy characteristic of men working in sanatoria for the tuberculous, they not only sent me answers to all my three questions, but many of my friends among the sanatorium directors have added individual expressions of opinion on the subject under consideration, of incalculable value because they were based upon actual, personal experience, in many instances covering a great many years.

From the oldest and best known institution, founded by our beloved Trudeau 25 years ago, Dr. Lawrason Brown, the resident physician, wrote me the following instructive lines. To question 1, he answered "no"; to question 2, he answered "yes," and added: "We have had a number of patients come to Saranac Lake village, form attachments and then finally on their turn for admission to the institution, get very much displeased with the strict discipline to which we subject them at first and leave because they wanted to arrange their life in a way of which we did not approve. Usually, after the patients have been here a week they are perfectly willing to stay. It is only at first that the trouble arises." To question 3, he answered "yes," and added: "There are a number of patients who have suffered from social and business ostracism, after having left the sanatorium either cured or improved. We have to take this into consideration in writing to our former patients and we make it a rule never to write on our letterheads the name of the institution or the name of Saranac Lake. Several patients have written to us complaining very bitterly that they have lost their places. For this reason we never publish in any paper or in any magazine, the name of any patient who has ever been connected with the institution. There is no doubt there is a general feeling against the tuberculous patient, whether well or not, whether careless or careful. I believe, however, that as knowledge spreads, there will be less trouble but certainly to-day there is a great deal."

Dr. G. Walter Holden of the Agnes Memorial Sanatorium at Denver, Col., answered to question 1, "no"; to question 2, "no"; to question 3, "no," and added: "On the contrary, people owning homes and wishing to take boarders have frequently written or telephoned me that they would be very glad to take patients leaving the sanatorium, as they felt very much safer in so doing than to take health-seekers coming to Colorado and not having had sanatorium training. In health communities, like Denver, certain hotels and boarding houses advertise that they do not accept tuberculous patients. While this is not always borne out by facts, it has a tendency to make tuberculous people more or less dishonest in denying that they have the disease, knowing that they can obtain admittance to these places by stating they have bronchitis or asthma, if they have any suspicious symptoms at all. I am of the opinion that our tuberculosis associations do not go quite far enough in their instructions and statements to the public. A recent example of this that has come to my attention is the case of a young man from New Jersey, who, while an incipient case, was not willing to make the fight to recover his health. The limited statements and injunctions regarding the disease that had come to his notice had made him feel like a leper or outcast. He was swallowing his sputum because he so interpreted a statement on the back of a street car transfer to the effect that spitting was prohibited. A great deal of the literature handed out by health organizations has a tendency to make the afflicted feel that they are more or less ostracized, because of the incomplete knowledge gained, and this interpretation is accepted by most of the general public not familiar with the disease. I also think that those of us who are working with tuberculosis all the time are somewhat inclined to overlook the fact that notwithstanding the wide campaign that is being carried on, the general public is so profoundly ignorant that our technical advice frequently overshoots the mark."

Dr. W. Jarvis Barlow of the Barlow Sanatorium at Los Angeles, Cal., answered to question 1, "no"; to question 2, "no"; to question 3, "no," and added: "We do not know of any case in which a patient after his discharge from the Barlow Sanatorium has suffered any degree of ostracism, either social or business detriment. On the contrary, many instances might be mentioned in which individuals have profited in this respect as a result of previous residence in the sanatorium, *e.g.*, nurses who have been led to the possibility of better employment when they were known to be so-called 'cured cases.' We find that the intelligent public is ready to accept the assurance of physicians that any patient is well and no longer a source of danger to the people about."

Dr. M. J. Brooks of the Brooks Sanatorium at New Canaan, Conn., answered to question 1, "no," and added: "There certainly cannot be a case here of infection between the patients or any of the staff. The discipline would preclude the very thought of such a proposition." To question 2, he answered "no"; to question 3, "no."

Dr. Jas. D. Brooks of The Bungalows, San Angelo, Texas, answered to question 1, "no"; to question 2, "no"; to question 3, "no," and added: "To the best of my knowledge there has been no such instance. With respect to San Angelo and the vicinity quite the contrary is true, a patient discharged from the institution being received universally with greater readiness than people only suspected of having tuberculosis."

Dr. Alexius M. Forster of Cragmor Sanatorium, Colorado Springs, Colo., answered to question 1, "no"; to questions 2 and 3 he answered "yes," and added: "I feel that the second question, as well as the first, still tends to keep many patients out of institutions. The sanatorium is frequently associated in the patient's mind with the poorhouse or the insane asylum. In the East in my work with the poorer classes I frequently had to deal with an unreasoning fear of all institutions, while out here with the well-to-do I often find that they prefer boarding-house life. While the fear of stigma attached to sanatorium life does not altogether account for this attitude, I am sure that it plays quite a part. Some patients often try to keep up the pre-

tence of refusing to admit, even to themselves, that they have tuberculosis, and others, while acknowledging it to themselves, refuse to admit it to others. In considering the subject I am sure it has occurred to you that a great deal of harm results from this attitude. I have known of boarding houses and hotels where sputum cups and all sanitary precautions are tabooed, and where patients in order to gain admission are compelled, not only to lie, but also to disregard all sanitary precautions. On the other hand, familiarity breeds contempt, and in some of our resorts there are many places where sanitary precautions are either very lax or are disregarded simply through carelessness. In regard to the third question, I can recall a number of cases where former patients were refused employment because of the fact that they had had tuberculosis. This, of course, was not because they had been inmates of institutions, but only because their residence in such a place published the fact that they had had the disease. The above applies particularly to women who seek employment in the home, and in my experience more rarely affects men. In this connection I should like to call your attention to the policy of certain institutions of refusing to employ persons who have tuberculosis. It has always been my policy to give the preference to those who had the disease, always provided that they were in a condition to work. It is true that such a policy is more expensive and requires a great deal more worry and supervision on the part of those in charge. But I have always felt that since we send our patients out to take their places in the world it is our duty to prove that they can be restored to a condition of economic usefulness, and surely there is no better way of proving this than by force of example. I feel that the wonderful campaign of education carried on by yourself and the other leaders in our work is doing much to get rid of the ignorance and prejudice with which your paper is to deal, but it is only by constant reiteration of the simple truths that the end will be reached."

Dr. Martin F. Sloan of the Eudowood Sanatorium, at Towson, Md., answered to question 1, "no"; to questions 2 and 3 he answered "yes," and added: "We have had during the period of two years at least twenty cases to leave because they were afraid they would develop more trouble than they at that time had. This has been especially true in our advanced wards where the ambulent cases become frightened at the bed cases, though the former might have as much involvement as the latter, even if their symptoms were not as pronounced. Several ex-patients have told me of their difficulty to get suitable lodgings on account of their having been in a sanatorium. One man was forced to leave three different houses after it became known that he had been at Eudowood. Two known cases have had to seek employment elsewhere. On the other hand, however, I have been glad to learn from several business men that they would willingly employ patients, as they felt that they would be a valuable asset among their working men rather than a detriment, as they had had instructions on lines of prophylaxis and sanitation. I might add further that it seems to me that during the last year some of this phthisiophobia has disappeared and this can be attributed, I believe, to the wide publicity that has been given to this sanatorium and the methods pursued here. Of course, I am speaking of conditions as they come to me."

Dr. Theodore B. Sachs of the Edward Sanatorium at Naperville, Ill., answered to question 1, "no"; to question 2, "no," and to question 3, "yes," adding: "Some orphan asylums or homes reluctantly readmit or refuse admission to children discharged from sanatoria; they do not inquire if the case is open or closed; the mere fact of their having been in a sanatorium bars them. We had to do considerable educational work among the managers of such institutions to have them differentiate between communicable and non-communicable cases, 'closed and open cases.' Considerable educational work must be done among employers of labor. This we are trying to do now through the medium of the committee and factories. Much of the unjustified fear is due to the fact that the patient frequently does not know the nature of his ailment; the doctor considers it a good policy to call it 'a cold,' 'bronchitis,' etc. When the sanatorium man examines the patient he is frequently warned not to tell the patient the nature of his trouble. We certainly agree that the patient should know the diagnosis, that the diagnosis should be stated in a kind, encouraging way, and that with the patient knowing the nature of his ailment, his cooperation is more readily secured and the battle is half won."

Dr. David R. Lyman of the Gaylord Farm Sanatorium at Wallingford, Conn., answered to question 1, "no"; to questions 2 and 3 he answered "yes," adding: "Quite a few patients have left on account of incompatability of other patients. Only closest care in placing patients can guard against this. The occasional careless patient (which we meet at times in all sanatoria) makes me quite a little trouble in this way. As a rule the friends and fellow employees of our discharged cases have been most ready to extend full cooperation to these cases after their return to work. In a few cases, however, this ostracism has been carried to the point of absolute cruelty and is by no means a negligible factor. The worst case of this I have known of was incited by the doctor who was the local health officer!"

Dr. Ralph Apted of the Grand Rapids Municipal Sanatorium, Mich., answered to question 1, "no"; to question 2, "no"; to question 3, "no."

Dr. Horace Greeley of the Hill Crest Open Air Sanatorium at Hackensack, N. J., answered to question 1, "no"; to question 2, "no"; to question 3, "no."

Dr. Robert B. Homan of the Homan Sanatorium at El Paso, Texas, answered to question 1, "no"; to question 2, "yes," and added: "I had one patient leave the institution after being here only one night, giving as a reason that she could not stand to be around so many sick people, but she has engaged a room to try again right soon." To the third question he replied "no," adding: "I have never found that the fact that I had suffered with tuberculosis and had spent nine months in a sanatorium has had any effect upon my reception into society or the business world. Of course, this is a health resort town, and a large percentage of our population come here because of the health of some member of the family, and on that account conditions may differ in the East, but I do not believe that the fact that one has had tuberculosis would incline people to refuse to accept them into social or business circles any more than would typhoid or any other serious illness."

Dr. Herbert M. King of the Loomis Sanatorium at Liberty, N. Y., answered to the first question "no"; to question 2, "yes," and added: "Very

rarely some hypersensitive and neurotic patient has left the institution very shortly after admission, ostensibly because of the associations. Such patients are not desirable in any case, and the few who make up the number would probably not benefit by sanatorium residence. It has been my intention to get an expression from several patients who have come into the sanatorium reluctantly and with more or less antipathy, and who have, as is usually the case, been won over to the enthusiastic cooperation in treatment, but I have not as yet had an opportunity to get more than two, which I enclose herewith. One is, as you see, from Miss X, a rather intelligent young woman connected with the Metropolitan Life Insurance Company, who had to be almost coerced into coming. As you see, she is in our intermediate division. The other letter is from Miss Y, whom you know, a sister of Dr. Y. She has just left the sanatorium 'apparently cured'—probably to resume her teaching next fall. She has always been reasonable, and this note of hers, which came unsolicited, gives you an impression of what an intelligent, educated and, at the same time, sensitive Quaker girl thinks of us:

" 'My dear Dr. King:—I have been thinking over some of the harsh and unkind thoughts that I had in mind about sanatoriums when I first heard I had to come to Loomis, and thought you would like to know how my opinions have changed. I could almost picture a place where there were so many very sick people; so ill even in their appearance that it would only make me feel worse to have to mingle with them. Instead I found many congenial people, with red, rosy cheeks, and able to do as much, even more than I could myself. I have been here at Loomis just nine weeks and have gained in weight, health and appearance, and in every way have felt the benefits of Loomis. I also realize that the rigid discipline, careful medical attendance, regular meals, exercise and sanitary habits are the cause of my improved health and know that we could never follow the same rules at home, no matter how good our intentions. Trusting that anybody with the same fixed, disagreeable thoughts that I had before entering Loomis will benefit by my experience and find the pleasant surprise that is in store for them to aid in regaining their health,

" 'Very sincerely,

" 'X.'

" 'My dear Dr. King:—Though I thought of no more questions that I wanted to ask you, I intended to try to see you in the evening to bid you good-bye, but it did not come to pass; so I am writing to tell you that my long stay at Loomis has been really a happy one, for the most part at least, and that I shall have many pleasant memories of it, including you and your kindness to me. With many good wishes to you personally, and many thanks for what you and the place have done for me, I am

" 'Very sincerely yours,

" 'Y.' "

Dr. Estes Nichols of the Maine Sanatorium at Hebron, Maine, answered to question 1, "no," and added: "We never have had any case of infection by visitors or employees during their residence at the sanatorium or any that have developed after leaving the sanatorium, which covers a period of eight years. We have to be on the constant watch, however, in employing help in all departments, because we find that many persons that fear that they have tuberculosis or perhaps have shown some signs, such as loss of weight, cough, expectoration, blood spitting, or a general rundown condition, as they speak of it, are apt to apply to the sanatorium for work. They frequently say that they have never had any trouble, but it only takes a short period of observation to realize that their attention has been drawn to their chest by one of these signs. I have in a number of instances examined the sputum of employees who have been in the sanatorium for less than two weeks and have found abundance of bacilli in it, and when we have accused them of knowing they had some trouble they frankly admit it and throw themselves on our mercy. This is one reason why the management of sanatoria should be very careful in engaging help without knowing whether they are free from tuberculous disease or tendency. We have been convinced to our satisfaction that the sanatorium is a very safe place to be in, and I think that is the experience of every worker." To question 2 he answered "yes," and remarked: "I have occasion to see a great many patients who have failed to come to the sanatorium early enough because of a feeling of danger. This has been confirmed in many instances by the family physician. When the case gets far enough advanced at home, however, they lose their fear, but in most of these instances we are unable to help them on account of this delay. This feeling is one that should be overcome, especially with the medical profession. We have had but two patients who have left the institution shortly after arrival because of this fear. One of these cases was an advanced case, and I think that most of the patients were glad that she did not remain." To question 3 he answered "yes," and added: "I know of occasional instances of patients leaving the sanatorium with the disease arrested and being ostracised, mostly in a social way, but relative to arrested cases it is more apt to be the other extreme. In other words, it is more difficult to hold a patient down for a sufficient length of time because of the friends ridiculing the idea of their having 'real tuberculosis.' With the few cases who go out with the disease progressive there is not enough ostracism in many instances to make the patient careful. Ostracism has one good feature with these persons. It holds them up to a degree of carefulness that convinces their friends there is no danger. Some persons are apt to feel that this is a hardship, but I find in the patient body under treatment ostracism of careless patients by the patient body will have more to do in making that patient more careful than anything else. I do think there is a good deal of needless fear concerning the disease, and sincerely hope that your paper will bring out many of these points."

Dr. Victor F. Cullen of the Maryland Tuberculosis Sanatorium answered to question 1, "no"; to question 2, "yes," and added: "We have had one patient, a far advanced laryngeal case, who thought that there was nothing the matter with her, and she objected to the association of the cases in the pavilion, and went home on this account." To question 3 he answered "yes," and added: "I know of several instances where patients have suffered ostracism because they have been at a sanatorium, although they left arrested and improved. This is mostly among boarding-house keepers, where, although the patient may have been at work elsewhere for one year, they were afraid to take them into their boarding house on account of their having had tuberculosis. I have seen several instances where boarding-house keepers would not

take in patients who had tuberculosis, and who used the proper means of disposal of their sputum and of taking care of themselves; yet these same people would take in an advanced consumptive, as long as he would sit on the porch and cough and expectorate on the lawn."

Dr. John Stewart of the Missouri State Sanatorium at Mount Vernon, Mo., answered to question 1, "no"; to question 2, "yes," and added: "The only cases I know of leaving because of the association with other patients have been neurasthenics of the worst degree, and in fact they have all been worse off than the patients they complained of and we are always pleased to see them go." To question 3 Dr. Stewart replied "no."

Dr. W. B. Kendall of the Muskoka Cottage Sanatorium at Gravenhurst, Canada, answered to question 1, "no"; to question 2, "yes," and added: "We have had one or two neurasthenics who have left the institution because they were not satisfied, but as for what the reason was I could not say; in fact, I feel that these patients should have gone to an asylum in the first place, as we were not prepared or equipped to take care of them. We find occasionally that some patients are naturally homesick for the first few days, when this soon wears off, and I feel that the moral effect of having other patients whose ideal is the same with them, is a great stimulus toward their following the treatment properly and getting good results. I consider this latter point to be one of the many reasons why patients can follow treatment to advantage in an institution rather than in the home." To question 3 Dr. Kendall answered "no."

Dr. E. S. Bullock of the New Mexico Cottage Sanatorium, Silver City, N. Mex., answered to question 1, "no"; to question 2, "no," and added: "Patients sometimes refuse to enter an institution because they think association with other patients would be unpleasant. After entering, however, I have never known one to leave on that account." To question 3 Dr. Bullock answered "yes," and added: "I have heard of many, many instances in which patients have suffered business and social ostracism, relatively or complete, which is the result of the medical profession's activity in promulgating ideas of the contagion of tuberculosis. Modern studies of tuberculosis have substantiated a growing conviction on the part of those most competent to judge that tuberculosis is a universal infection; that the worst thing that can happen to one is to be among the residual 2 per cent. who have not been infected in early life, for when infection occurs, which it is bound to do sooner or later, in the absence of the protective infection enjoyed by most people in early life, the result is a virulent type of tuberculosis which finds its analog in experimental tuberculosis in animals."

Dr. Marion H. Ober of the Portland Open Air Sanatorium at Milwaukie, Ore., answered to question 1, "no," saying "I want to say that for five years now I have been connected with tuberculosis sanatoria in the South, West and here, and have come very closely in touch with the patients both incipient and advanced cases (mostly the latter), and have not as yet become a victim to the disease." To question 2 he answered "no," and added: "No one has ever left on account of unpleasantness on entering the institution, and it is surprising how very quickly they adapt themselves to the open life. Very few patients have returned to their inside occupations after leaving (not that they have left for heaven), but have gone on to the different ranches or into real estate and other occupations that keep them out of doors." To question 3 he answered "no," and added: "If people feared more the crowded churches and theaters and realized the sanitation of the various sanatoria we would have less difficulty in convincing our patients that there was less danger at sanatoria than at their own home."

Dr. F. M. Pottenger of the Pottenger Sanatorium, Monrovia, Cal., answered to question 1, "no"; to question 2, "yes," and added: "I recall only two who felt that they were obliged to leave the institution because they found the association unbearable, but I would like to say that these same two patients found the association at home unbearable and made it unbearable for those around them; in other words, they belong to the discontented class. The general rule is that the fear of the sanatorium being unpleasant and obnoxious nearly always disappears after a day or so in the sanatorium. Some of those who have feared coming the most have been the most ardent supporters of the institution after their arrival." To question 3 Dr. Pottenger answered "yes," saying: "There is a great prejudice among the laymen against the tuberculous patient, and the laymen, unfortunately, do not differentiate between the trained patient and the untrained, neither do they differentiate between the patient who is in the open stage and the one who has secured an apparent cure. The very fact that the patient has been in a sanatorium or has taken treatment from a physician who is a specialist in tuberculosis brands many of them and works injury against them when it comes to their association with the outside world. This is carried on to such an extent that I often find it best, in corresponding with my patients, to use plain envelopes in order to conceal the fact that the person with whom I am corresponding has had anything to do with me. . . . I believe that we can do just as much for the prevention of the disease and just as much for its cure and inject far more humanity into the problem by making greater efforts against the unjustifiable phthisiophobia which now exists. I hope that your paper will have wide circulation and do much good along this line."

Dr. P. H. Bartlett of the Rutland State Sanatorium, Rutland, Mass., answered to question 1, "no"; to question 2, "yes," and added: "There have been a few cases that came to my notice where patients were not satisfied because they were obliged to be in an open ward with others. In most instances, however, these patients became accustomed to the routine and stayed. I believe a few, however left for this reason. In most instances I do not think it was because they were associated with other tuberculous patients in rather close proximity, but because they were nervous and not accustomed to being with so many people during their sleeping hours." To question 3 he answered "yes," and added: "It has happened, not infrequently, that some patients after leaving the sanatorium have reported that they have been troubled about getting employment or that they have had trouble with their fellow employees because they were tuberculous. In all of these instances I have given a certificate stating that I felt that a conscientious, well trained tuberculous patient, although there might possibly be some activity of the disease present, was not a menace to the community, and that I felt that our 'arrested' cases were in no way dangerous."

Dr. Oliver T. Hyde of St. Joseph's Hospital, Silver City, N. Mex., answered to question 1, "no"; to question 2, "no," adding: "The general atmosphere is cheerful and optimistic." To question 3 he answered "yes," and added: "I have noted that some patients, having obtained a partial or complete arrest, and desiring to live in private dwellings in the town, have been discriminated against because of their sanatorium history. This, though, is the result of ignorance. On the other hand, I have found that arrested patients whom I have recommended to responsible business men for positions and in whom it was possible for me to say that the lesion was not active and the sputum was negative were perfectly satisfactory to the employer, and they have obtained positions where in the ordinary course I am quite certain they would not."

Dr. Vincent Y. Bowditch of the Sharon Sanatorium, Sharon Hill, Mass., answered to question 1, "no"; to question 2, "yes," and added: "Homesickness and nervousness due to the mere presence of others, apart from fear of infection, have been occasionally causes for patients leaving. The number of those who have left from mere fear of infection has been very small, so far as we have been able to determine; and while I have had a good many who in applying have expressed this fear, the majority have ceased to harbor such thoughts after intelligent instruction during their stay at the sanatorium." To question 3 Dr. Bowditch answered "yes," and remarked: "I have known of a few such cases among the many hundred who have left the sanatorium, and I believe there is, unfortunately, ground for patients feeling that they may be ostracised if they have been in a sanatorium. To a certain extent, in my opinion, this is inevitable on account of the irrational, cruel and unnecessary attitude, which I deplore and deprecate, taken by some people who deal with former patients, no matter how well they are, who are not only not sources of danger, but who, from their knowledge of how to take care of themselves and others, act as missionaries among those with whom they associate."

Dr. Geo. M. Sternberg of the Starmont Sanatorium, Washington Grove, Md., answered the three questions with "no."

Dr. Lawrence F. Flick of the White Haven Sanatorium, White Haven, Pa., answered to question 1, "no"; to question 2, "no," and added: "So far as I know no one who has entered the sanatorium and has remained long enough to become acquainted has left on account of association with other patients. This is the more remarkable since at White Haven Sanatorium there is no discrimination as to race or color, and we frequently have colored patients side by side in the same ward or in the same room. We also have had Chinese and Japanese mixed in with the other patients." To question 3 Dr. Flick answered "yes," saying: "I have heard of business ostracism after leaving the sanatorium, but I do not know of authentic cases. White Haven Sanatorium has made it a rule to protect the patients as far as possible by guarding their identity and refusing information about them to all inquirers except the family."

To summarize the foregoing answers we may say that to question No. 1, asking whether any healthy individual had ever contracted tuberculosis during his sojourn in the sanatorium, all twenty-five sanatorium directors to whom letters were addressed answered "no." To question 2, asking whether any newly arrived patient had left the institution because he found the association with other patients unpleasant, 13 answered "yes," 12 answered "no." To question 3, asking whether any patients had suffered social or business ostracism after having left the sanatorium, 13 answered "yes," 12 answered "no." The additional remarks of the sanatorium directors, besides their value as answers to my questions, are, of course, highly interesting and instructive, and they speak for themselves. May I now, in conclusion, say a few words regarding my personal experience relating to this topic?

My experience during the relatively short time I served as assistant in a sanatorium, corroborates the negative answers to question No. 1. For my doctorate thesis before the Faculty of Paris, entitled, "Les Sanatoria, Traitement et Prophylaxie de la Phtisie Pulmonaire," published as far back as 1895, I had similar answers from twenty-five of the leading European sanatoria. During the many years that it has been my privilege to be the senior visiting physician to the Riverside Hospital-Sanatorium for Consumptives of the New York City Health Department, where the great majority of patients are in the advanced stages and come mostly from the ignorant and poorer classes, there has never been an authentic case of tuberculosis having been contracted among my assistants and nurses. This result in a hospital for advanced cases is, I believe, even more remarkable. Regarding the matter referred to in question 2, I am willing to make the statement that not only will much depend upon the atmosphere of cheerfulness which the sanatorium director can create by his own personality and his example to his assistants, nurses, helpers and patients, but also upon the physician who sends the patient to the sanatorium. Let the physician impress the patient with the idea that the sanatorium is "eine Heilanstalt"—a healing institution—that he must expect to see sick patients, but that by his own hopefulness, cheerfulness, and determination to get well, and his ready compliance with the sanatorium rules he can be productive of immeasurable good to himself and others. During my stay at Falkenstein as assistant to that immortal teacher and pioneer of the sanatorium treatment, Dr. Dettweiler, I had occasion to witness manifestations of the greatest sympathy, particularly on part of the well-to-do patients toward their financially less fortunate brethren. It was there at that time that a few wealthy patients expressed their gratitude for a complete recovery by presenting Geheimrath Dettweiler with a large sum of money for the purpose of establishing an institution similar to that of Falkenstein for the consumptive poor. This institution, the first in Germany for the tuberculous of limited or of no means, is now located at Ruppertshain, a short distance from the mother institution, and is one of the most flourishing and successful of all the European sanatoria.

Apropos of the antipathy some individuals have to entering a sanatorium let me relate a true story which was communicated to me only last week. A patient whom I had sent to one of our leading sanatoria returned to me completely cured after a prolonged stay at the institution. I mentioned to her the subject of this paper, whereupon she told me the following incident which she had recently witnessed: A young woman in a rather advanced stage of the disease had entered the sanatorium two years before, much against her wishes and inclinations. On her arrival she was sure that she could not stand the environment and was prepared to leave as soon as she was rested sufficiently to take

the homeward journey. But she began to improve, though slowly, and she soon realized that the place was not half as bad as she had imagined it to be. She became one of the most faithful and obedient patients, carrying out with enthusiasm the orders of the physician. It took two years to cure her, and the other day, when her physician at last told her "You are cured; you can go home," she rejoiced, of course, but when the time for her departure came she shed bitter tears over leaving the place where she had been so happy and contented, where she had regained her health, and had made so many friends. My narrator said that the adieus were pathetic in not a few instances, and when recalling her own farewell from the institution, I noticed a moisture in her eyes. I believe all objections to entering and remaining in a sanatorium can be overcome if the physician can be persuasive enough to make the patient perceive that he has now a mission before him not only to help himself but to help others as well, and that by the knowledge and training he will receive in a sanatorium he will become a sanitarian, a hygienist, a factor of real good to his fellowmen, particularly among those to whom he will return after his restoration to health. I really think that I have won over many a patient to the sanatorium idea.

My experience with the more advanced cases coming from the poorer classes has, however, convinced me of one fact which I fear our authorities do not take sufficient cognizance of. If we wish to retain an advanced case in a hospital for isolation we must make the environment of this patient as attractive, as pleasant and as sympathetic as possible. If we fail to do this the advanced case will prefer to do with a little less comfort, in fact even to put up with less good food, a less clean bed, and less pure air, if he is only allowed to die in his home.

And now a last word concerning the social and business ostracism to which discharged patients are alas, so frequently subjected. Wherein lies the remedy for this type of phthisiophobia? I do not quite agree with some of my colleagues who hold the campaigns of our health department responsible for this type of phthisiophobia. In all the health department literature which has come under my observation the statement that the clean, conscientious consumptive is as safe an individual to associate with as any one else has always been emphasized. It is rather that the employers should be convinced that a tuberculous patient, even if his case is not arrested and not completely cured, or when the cure is only an economic one, is best fitted by his training in the sanatorium to become absolutely safe to associate with, if the hygiene in the factory, workshop or office is not so bad as to make everybody sick. We not only need a little more education, but also a little more charity toward our consumptive fellowmen. The tuberculosis problem will not be solved by phthisiophobia but by a humane, just, sympathetic and helpful attitude toward patients within and outside of institutions. Fortunately this world is growing better and I for one at least see brighter and happier prospects for the patients entering and leaving sanatoria. As stated above, when they are rightly taught and rightly trained they are bound to become the most valuable coworkers in our labors, particularly so when they are imbued with the idea that though they may be seemingly disabled, they are still valuable and useful members of society. Let them feel that they may join in what is a sacred mission to all of us, namely, service to men, which in the end is the highest service to God.

THE RELATION OF DIET TO HEART AND BLOOD-VESSEL DISEASE.

By LOUIS FAUGERES BISHOP, A.M., M.D.

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASE, FORDHAM UNIVERSITY SCHOOL OF MEDICINE; NEW YORK CITY; PHYSICIAN TO THE LINCOLN HOSPITAL.

Diet is a great though puzzling subject and has a very important bearing upon the treatment of disorders of the heart and blood vessels. The trouble with the question of diet is that on the one hand it is so simple and easy to understand that we overlook it from its very simplicity; and on the other hand, the chemistry of food and nutrition is so complicated and hard to master and there are so many points beyond our present knowledge that we are appalled when we attempt to fathom it.

On the foundation of the ultimate composition of food and on a foundation of practical experience with the feeding of healthy and diseased persons under different conditions, the question is very simple.

So if we are willing to take the ultimate composition of food as our foundation and make the matter of feeding under all conditions a matter of arithmetic, modified by certain common sense principles pertaining to individual experience, the question of the quantitative regulation of food may be made a very simple one indeed. However, one should never undertake the treatment of serious heart disease by a *specific diet* unless the blood can be examined at least twice a month and the weight constantly watched.

In considering food we need take account of only four or five ingredients. We need to take account of the protein, of the carbohydrates, and of the fats. The amount of water in food is a matter of indifference. The amount of salt and ash bears such an indefinite relation to nutrition and health that in a mixed diet we can also generally ignore them. There is no doubt that there are certain numerous food ingredients that are required in small quantities. These are provided for by the incidental articles of food that anyone gets as a matter of occasional indulgence for the sake of variety.

I had a patient a few years ago with a typical attack of scurvy because he was a bartender and got his food from the free lunch counter, which was of course short on vegetables, which we know prevent scurvy.

So a certain amount of variety is necessary in all dietaries.

In heart and blood-vessel disease, particularly in the more advanced stages, diet is more than half of the whole treatment. This is true because cardiovascular disease has its origin more than half the time in errors of diet. There is no doubt that the increase of cardiovascular disease as shown by statistics is, in a great measure, due to the altered dietary of the present generation. Formerly a man who wrested his living from the soil got enough exercise, he was always well supplied with an abundance of vegetable food, and he escaped the consequences of a diet too rich in protein, and the consequences of the suboxidation of his food.

While everyone recognizes the relation of diet to advanced cases of cardiovascular disease which are essentially cases of Bright's disease, the relation of diet to the purely valvular cases is not always so plain. A young man whom I saw recently had a very severe form of chronic rheumatic endocarditis that has resulted in the destruction, in a measure, of

both the aortic and mitral valves. He is a very ambitious young lawyer, and it is particularly unfortunate that he has developed these very severe lesions just as he begins his career. This boy had been under treatment for his heart before he came to me and had not been doing very well. I discovered that in addition to his chronic heart trouble he was suffering from chronic intestinal putrefaction, and that it was the resulting chemical poisoning of his heart muscle that was preventing him from developing a satisfactory degree of compensation. The outcome proved the conclusion, because on a very careful diet this young man has been able to resume his law practice, and his heart, instead of growing worse, is improving.

The relation between the intestinal food activities and the heart muscle is something that is brought to my notice not every day but several times every day, so that I am absolutely convinced of the relationship. The integrity of the heart muscle is more often impaired by the effects of the overingestion of food, or the ingestion of the wrong kind of food element than for any other reason. In private practice this is a common cause of disturbance of the heart muscle. Very often we hear of the death of a prominent man after a big public dinner. The former explanation, and I believe the popular explanation at the present time, is that the man died of an attack of acute indigestion exhausting his strength and leading to his death. I do not believe that the result is so indirect. I believe that these deaths must be laid to the account of acute autointoxication from the rapid disintegration of an excess of protein food.

In my own practice I see a great many examples of acute poisoning of the heart muscle by the products of intestinal putrefaction.

A young man who was under my care last winter developed a mania for eating meat. He would eat his breakfast composed of meat; in the middle of the morning he would go out and get a meat sandwich; he would also have meat for his lunch, in the afternoon, for his dinner, and late at night. He consequently developed an intense autointoxication, and when I first saw him his heart was beating only about forty to the minute and was extremely feeble and irregular. It was necessary to put him in a hospital and treat him heroically or he would have drifted on to a fatal termination.

We learn principles from extreme cases, and we must apply these principles to our milder cases in which the relation of cause and effect is not so apparent.

A young man, otherwise healthy, leading an active life, can consume with impunity an amount of food several times as great as his bodily requirements. Professor Atwater estimated the food intake of some of the students of Wesleyan University, and he found this was something enormous; it was perfectly incomprehensible that the human body could tolerate and dispose of such an excess of food. So the question of food with young people is not so eminently important. However, I recently saw a young man, a Princeton boy, who was very much out of health on account, in a great measure, of eating just about twice as much food as he needed. He had developed some nervous symptoms and weakness of the heart.

When we consider the question of the feeding of heart and blood-vessel patients, the only thing to do is to put the whole question on an arithmetical basis. The arithmetic of food is founded upon definite experience in the feeding of large bodies of men, in the dietetics of institutions, and in individual observation. Diet, twenty-five years ago, was purely a matter of fad. One group of people called themselves "vegetarians," another group took other food and called themselves something else, and so on. There is no reason for these fads because it is not a question of preference for vegetable or animal food, but a matter of the ultimate analysis of food of every kind.

The whole principle of dieting in people with impaired circulation is in regulating the amount of protein and calories so that the patient has what is required, but has nothing in excess of his requirements. The exception to this is where one can trace the cause to a particular proteid food. The few-proteins diet that I have recently advocated offers a good chance that particular unfriendly proteins may be excluded though they may not have been unsuspected of doing harm.

A physician who came under my care several months ago was in the last stages of what is popularly known as Bright's disease. His blood pressure was over 200, he had shortness of breath and hypertrophy of the heart, and he was passing a very large quantity of very light urine; he also had signs of impaired circulation in his central nervous system, represented by mild symptoms pointing to hemiplegia. Altogether he was a most distressing object from the point of view of doing him any good. However I found that his diet was absolutely wrong. He was consuming about 250 grams of protein and 3500 calories. The rule in such cases is to reduce the diet to 50 grams of protein and 2000 calories. This man submitted to this rigid diet and he improved a great deal so that he was able to do his work with some degree of ease, and he managed to pull through the winter all right. Unfortunately he did not adhere to his diet and after neglect of the latter for a few weeks he had an attack of apoplexy which caused interference with locomotion and with the power of speech. Again he went on the diet and again he improved. In a few weeks I saw him again and he had lost ground. As soon as I saw him I said: "You have been neglecting your diet," because I found that his blood pressure was 230, and his whole appearance showed the toxemia of chronic nephritis. He said in reply: "Well, yes, I have been eating meat several times a day," and so on. When he had gone I called up his wife on the telephone and she told me that of late he had not only eaten big meals, but had gone out to get things to eat between meals. It is a very common occurrence that people with the impaired mentality that goes with degeneration of the blood-vessels develop an abnormal appetite, and a great many of these patients, in spite of every intelligent effort exerted in their behalf, simply commit suicide by poisoning themselves with food.

On the other hand, I have seen men just as bad as this patient in the beginning, reduce themselves to a diet of 50 grams of protein a day, and with plenty of outdoor exercise go on for years in a condition of equilibrium and never have apoplexy or any other accident.

The ideal diet or the key to an ideal diet for a patient with heart and blood-vessel disease is bread and butter, with a certain amount of milk to supply the fluid, and enough cheese to make up the protein requirements, without an excess of carbohydrates or heat units. If a man is fed on bread

and butter alone he gets an excess of carbohydrates which burdens his digestion. It leads to an accumulation of weight and other evils, but if given bread and butter in moderation, with cheese to furnish the necessary protein, he gets along perfectly well on this balanced ration, which is a very good ration indeed. On account of the scurvy question it is necessary to add fruits and green things, but the essential elements may be obtained from cheese, milk, and bread and butter.

The main point is the food people consume habitually—what they take one day after another. In a reservoir it is the income and outgo day in and day out that determines the fullness of the reservoir. A thunderstorm may fill it up, or an extra drain may empty it, but it is the everyday thing that counts. It is very hard to induce people to take an average amount of food of the right composition. I have often heard an old Irishman say that "it does a man good to get drunk once in awhile"—that it is good for his health. While I do not like to advocate this rather sweeping theory, however, an occasional food debauch does not affect a sound man very much, but if he is diseased it is apt to be too great a strain on his heart.

The amino acids of protein digestion and their relation to the integrity of the liver furnish the key to some very bad cases in which a mere balancing of ration fails, but the discussion of this subject is beyond the scope of this paper.

54 West Fifty-fifth Street.

VACCINES IN SUPPURATIVE OTITIS MEDIA.*

By ARTHUR C. CHRISTIE,

CAPTAIN, MEDICAL CORPS, U. S. A.

During the past two or three years considerable work has been done by a number of different observers in efforts to determine the effect of vaccines on suppurative disease of the middle ear. The writer was among the first to publish case histories (*Journal American Medical Association*, February 26, 1910) of otitis media patients treated with vaccines, and wishes at this time to give the histories of some instructive cases, and to state his conclusions, after considerable experience, on the use and limitations of autogenous vaccines in suppurative otitis media.

The first point to be insisted upon, and one which has been emphasized by nearly everyone who has written on the subject, is that the vaccine must be so prepared that it contains the causative organisms of the disease. This would seem to be a very self-evident proposition, and yet there are those who declare that vaccines have no value in this condition on the ground that they had taken some pus in a haphazard manner from the external auditory canal, and had treated cases of otitis media successfully with a vaccine made from organisms obtained from it. It should not be forgotten that the external auditory canal usually contains many different germs, and if an attempt is made to cultivate the organisms of an existing otitis media from its contents the culture will nearly always be contaminated with several other varieties, and the causative germ will often be outgrown by some harmless saprophyte. Sometimes the contaminating organism will be a spore-bearing bacillus and it will be impossible to sterilize the vaccine without overheating it. In the writer's work the attempt to obtain the causative organism is made by first thoroughly irrigating the external auditory canal with salt solution, drying it with sterile cotton, and then, under good illumination, taking some of the discharge from the opening in the drum, the patient forcing it out by autoinflation, or Seigel's speculum being used to draw it forth. Even with care, however, it is often necessary to make several attempts before the offending germ is found, and in some cases there is no doubt that it never is obtained.

The following case, which I will report in detail, shows particularly well the importance of making the vaccine from the proper organism. Each c.c. of the vaccines used in the cases reported in this paper contained 250,000,000 organisms.

Case I.—G. C., age 21. Admitted to hospital on December 31, 1911, with measles. January 9, 1912: Has had pain in right ear since yesterday. Right drum is red and bulging. Incision is followed by thin purulent discharge. January 12: Profuse purulent discharge from ear. Fowler's suction douche is used daily, ear thoroughly dried, and sterile wick inserted. January 13: No change. Same treatment. Culture made for vaccine. January 15: Profuse discharge. Same treatment.

January 17: Profuse discharge continues. One-half c.c. vaccine given. The organism is staphylococcus pyogenes aureus in pure culture. January 18: No reaction from vaccine. Profuse discharge from ear. January 21: One c.c. vaccine given. Local treatment continued. January 22: No reaction whatever from vaccine. Profuse discharge from ear. January 24: New culture made for vaccine. In addition to the staphylococcus there is also present a small barred bacillus. A vaccine is made from this organism and mixed in equal quantities with that made from the staphylococcus. January 25: Profuse purulent discharge from ear. One c.c. of the mixture of the two vaccines given. January 26: Slight local reaction from the vaccine. Discharge about the same. Irrigation and inflation. January 27: Discharge markedly less in amount. January 28: Very small amount of discharge from the ear. One c.c. vaccine given. January 29: Pronounced local and general reaction from the vaccine. January 30: Slight discharge from the ear. Local treatment continued. January 31: Small amount of watery discharge. Suction with Seigel's speculum. Inflation through catheter. February 1: No discharge from the ear. One c.c. vaccine given. The drum looks white and edematous. February 2: Pronounced reaction from the vaccine. February 4: No discharge. Drum is still white and swollen. Inflation. February 5: Small amount of purulent discharge. One c.c. vaccine. February 6: Marked reaction from the vaccine. Considerable discharge.

February 8: No discharge. Drop of pus withdrawn with Seigel's speculum. February 10: No discharge. No pus on inflation. February 11: No discharge. One c.c. vaccine given. February 12: No reaction from the vaccine. No discharge. February 15: Perforation is closed and drum looks normal except for retraction. Inflation. February 18: Drum looks about normal: inflates readily. Hears whisper at twenty feet.

It will be noted in the above case that the first culture obtained was the staphylococcus pyogenes aureus, and in view of its well known activities, it was easy to believe that this organism was at the base of the trouble. When, however, its injection

*Read before the Columbus Academy of Medicine, Columbus, O., April 22, 1912.

caused absolutely no reaction, and no change was made in the course of the disease, it was concluded that some other organism must be the cause of the suppurative condition. Another attempt at cultivation revealed a small barred bacillus (unidentified). Injection of a vaccine made from a culture of this organism produced a local reaction and the suppurative condition underwent a marked change.

It may be well at this point to further analyze this case, it being an interesting one, and illustrates several points of importance. It was noted on January 26 that there had been "a slight local reaction"; by this is meant a slight redness at the site of injection, and some little local tenderness. In the writer's opinion this is the reaction always to be sought for after the first injection of vaccine, and with a little experience in preparing and administering vaccines it can nearly always be obtained. This is important because upon this reaction depends the time of administration and the size of the second dose. If nothing more than a local reaction is obtained then the second dose of 1 c.c. is given after an interval of four days. The frequency of subsequent doses must depend entirely upon the reaction obtained and the course of the disease.

It will be noted in this case that on January 26, the day after the initial dose of the effective vaccine, the discharge from the ear was profuse, but on the two succeeding days there was a marked diminution in quantity and change to a more watery character. This could be accounted for by coincidence, especially since the disease had been in progress for two weeks and might well be subsiding under local treatment. This, however, is the typical result obtained in practically all cases of otitis media where the vaccines are effective. There is first an increase in the amount of discharge and soon afterwards a marked diminution in quantity and change in character. The second dose of vaccine was given on January 28, and was followed by a pronounced general reaction; that is, the patient had a feeling of malaise and his temperature arose to 100. All symptoms due to vaccine disappeared in about twelve hours. On February 1 there was no discharge from the ear but the appearance of the drum showed that the disease had not entirely subsided. A third dose of vaccine on this date again produced a marked reaction. It may be stated here that so long as a reaction takes place after the injection of vaccine the disease is probably still active. Altogether this patient received five doses of vaccine and after the fifth had no reaction whatever. This dose was followed within two days by a complete disappearance of the disease, as evidenced by a drum which was normal in appearance except for slight retraction, the perforation having closed, and inflation being easy.

It can be said that this case might have recovered just as soon under local treatment alone. That, of course, is true, but it is equally true that it might not have, for there are many cases that never do recover under local treatment. No one can tell how long it will take to effect a cure in any case of otitis media under any method of treatment. The striking thing about the use of vaccines is not the length of time it takes to effect a cure, but rather the distinct change for the better which takes place after every injection of the vaccine. Even should it take equally long to effect a cure by the use of vaccines they still have an important action in so modifying the course of the disease as to prevent much of the destruction that would otherwise take place in the middle ear. The mere fact that the discharge is lessened in amount and becomes more serous in character points to a diminished activity of the disease. It is true that cases are occasionally encountered in which the vaccines have no appreciable effect. These can be accounted for on the ground that the causative organism was never secured, which is undoubtedly often the case, or that the disease was so active or of such long standing as to have produced necrosis of bone. Even in the latter class of cases a suitable vaccine is often of great benefit in so modifying the course of the disease as to prevent further destruction, and the involvement of neighboring structures.

There are many cases of otitis media which recover in from eight to twenty days under local treatment, especially if incision of the drum is practiced early; and others which recover under no treatment at all; but there are still others which persist in spite of the most painstaking care. It is in this latter class that vaccines find their legitimate field, and in a large per cent. of which they effect a cure. In the writer's work, after the first year or so, when it was largely experimental, vaccines have been used only in those cases which have shown themselves resistant to local treatment. When it becomes evident after ten days to three weeks of local treatment that the case will at least be one of long duration the use of vaccines is begun, the local treatment being continued. They are not to be used to the exclusion of other methods of treatment but only as an adjunct to the proper local measures in resistant or long-standing cases.

The local treatment in all of my cases consists in very early incision of the drum membrane, followed by daily, or more frequent, irrigation with Fowler's suction douche. The canal is thoroughly dried after each irrigation and a gauze wick lightly inserted. When the disease has somewhat subsided the eustachian tube is kept open by inflation through the catheter. Some of the cases which persisted in spite of these measures are given below, and the success of the vaccine may be judged from them.

Case II.—C. B., age 25. Admitted to hospital January 31 with measles. After aching for a few hours during the night, on February 5, the right ear began to discharge. Drum red and thickened, with a perforation considered large enough to afford adequate drainage. Local treatment was continued daily until February 16, and a thick purulent discharge still continuing, the patient was given ½ c.c. of an autogenous vaccine. This was followed on February 17 by a pronounced local reaction. On February 18 the discharge was much less in amount. On February 20 there was no discharge. No further treatment was given until February 26, when the drum looked normal except for retraction. It was inflated through catheter. Patient remained without symptoms until April 1, when he reported with roaring in the right ear. Drum was readily inflated by Politzerization and he experienced no further trouble.

Case III.—B. B., age 27. Patient discharged from hospital on February 1, after an attack of lobar pneumonia. On February 3 he reported at hospital with earache. The right drum was found red and bulging. Incision was followed by a serous discharge. The next morning there was purulent discharge from both ears, the left drum having ruptured during the night, the patient having had no

pain whatever in that ear. Smears show a diplococcus, resembling the pneumococcus, and a small bacillus. Local treatment was continued daily and on February 16, there being a very profuse purulent discharge from both ears, 1 c.c. of a vaccine made from cultures of the above organisms was injected. On February 17 a slight local reaction from the vaccine had taken place and the discharge was watery in character and not nearly so profuse. Local treatment was continued daily. On February 20 there was no discharge from the right ear and a slight watery discharge from the left. Two c.c. vaccine given. Patient not seen again until February 26, when there was no discharge from either ear. Both drums were retracted but readily inflated. No recurrence of the discharge took place.

Case IV.—L. H., age 21. Patient in hospital with measles when he complained of pain in right ear on April 25. On examination the external auditory canal was found full of pus. Daily local treatment was pursued. On May 14 there was still a profuse discharge and ½ c.c. of an autogenous vaccine was injected. A marked local reaction took place. On May 15 there was much soreness along the external auditory canal and at the meatus; this was thought to be a part of the reaction from the vaccine. The discharge on this date was much less in amount. On May 19 there was no discharge, the drum being uniformly red but readily inflated. May 31, the discharge had not recurred and the drum looked normal except for retraction. It was readily inflated and patient could hear a whisper at twenty feet.

Case V.—L. E. H., age 21. Admitted December 4, 1911, with measles. On December 12 the right drum was found red and bulging and was incised. December 13, profuse purulent discharge, accompanied by much pain and tenderness over the mastoid and drooping of the postero-superior wall of the canal. The suction douche and Seigel's speculum were used and on the next day the pain and tenderness over the mastoid had greatly subsided. The profuse discharge continued but the mastoid symptoms gradually disappeared. On December 24 the discharge stopped and the opening in the drum was found nearly closed. Another incision was made and was followed by a very profuse purulent discharge. During the next week the discharge continued in varying amounts. On January 3 there was not quite so much discharge but the case was progressing so slowly that ½ c.c. of an autogenous vaccine was given. This was followed by a slight general reaction. On January 4 the ear was perfectly dry and although the incision was well open nothing could be withdrawn with Seigel's speculum. On January 7 there was no discharge but the drum looked red and thickened and 1 c.c. of the vaccine was given. There was a slight reaction from this. The discharge never recurred. The drum remained retracted and inflation was somewhat difficult on account of the presence of a small amount of adenoid tissue which was removed on January 12. The patient went to duty on January 16 and had no further trouble.

Case VI.—H. S., age 21. Admitted December 13 with appendicitis. Appendix was found gangrenous and a large abscess surrounded it. On December 24 acute follicular tonsillitis began, and the next day the left ear drum was found red and bulging. Incision was followed by a free purulent discharge. On January 4 the discharge was still very profuse and ½ c.c. of a vaccine made from the *Staphylococcus pyogenes albus,* which had been obtained from the patient's ear, was injected. January 5, slight local reaction. Profuse discharge. January 6, almost no discharge. January 7, no discharge, drum readily inflated. One c.c. vaccine given. January 13, drum somewhat retracted but readily inflated. One c.c. was given and there was no reaction whatever. The patient was observed for about a month while convalescing from the appendiceal abscess and no further trouble was experienced with the ear.

Case VII.—S. G., age 20. Admitted to hospital with measles on January 23. February 5, right ear drum red and bulging; incision followed by purulent discharge. Local treatment pursued daily, but on February 23 the discharge continued unabated and ½ c.c. of an autogenous vaccine was given. The culture was *Staphylococcus pyogenes aureus.* Slight local reaction. On February 24 the discharge was about the same in amount but more watery in character. February 25, no change. February 26, discharge distinctly lessened in quantity. February 27, no discharge whatever. One c.c. vaccine given. February 28, marked reaction from the vaccine; slight watery discharge from the ear. February 29, ear perfectly dry. The discharge never recurred and the drum gradually returned to normal.

The next two cases show a very marked action of the vaccine, in that each of them cleared up after one dose, the discharge having continued for about five weeks in the first and three weeks in the second.

Case VIII.—A. B. February 5: Right drum red and bulging. Incision followed by purulent discharge. February 6: Profuse purulent discharge. Local treatment begun and continued daily until March 15, when the discharge still being very profuse 1 c.c. of an autogenous vaccine was injected. March 16: Local reaction from the vaccine. March 18: Very slight discharge from the ear. Local treatment continued. March 19: No. discharge. Perforation in drum is closed. Drum is red and thickened. March 23: Drum normal in color but retracted. Autoinflation easy. There was no recurrence of the disease.

Case IX.—F. K. February 28, 1911. Admitted to hospital with measles. March 13: Right drum red and bulging. Incision followed by purulent discharge. Daily local treatment was continued until April 4, when a culture showed presence of *Staphylococcus pyogenes albus* and a diplococcus. A vaccine was made from these organisms. April 7: Free purulent discharge from ear; ½ c.c. vaccine given. April 8: Local reaction from vaccine. No discharge from ear. April 11: No discharge. The patient made a complete recovery without recurrence of the discharge and without another dose of vaccine.

Case X.—L. H., age 18. Admitted to hospital December 3, 1911, with measles. On December 9 there was spontaneous rupture of the right ear drum, the patient not having complained of any pain in the ear. Daily local treatment was carried out. December 12 there was a very profuse discharge from the ear and considerable pain and tenderness over the mastoid, with drooping of the postero-superior wall of the canal. December 13, discharge about the same but less mastoid tenderness. Complained of pain in other ear and on examination the drum was found red and bulging. Incision was followed by purulent discharge. The

discharge was exceedingly profuse from both ears and continued in spite of careful local treatment. On December 27 both drums were reincised. On January 4, the discharge being just as profuse as at any time during the course of the disease, ½ c.c. of an autogenous vaccine was injected. January 5 marked local reaction from the vaccine. Slight watery discharge from the right ear; that from the left about the same as before. January 6, very small amount of purulent discharge from both ears. January 7, 1 c.c. vaccine given, followed by a slight local reaction. January 13, a slight watery discharge is still present. One c.c. vaccine given. January 17, no discharge from either ear. One c.c. vaccine again given. January 18, slight reaction from the vaccine. No discharge from either ear No recurrence of the discharge took place. On January 24 the perforations were closed, both drums being retracted but readily inflated. On January 25 autoinflation was easy in both ears and the hearing was 20/20 for the whisper.

Since December 1, 1910, the writer has treated seventy-six cases of acute suppurative otitis media, all of them among soldiers or their families at Columbus Barracks, O. Thirty-nine of these cleared up completely in from one to three weeks under local treatment alone. Three died of bronchopneumonia, this as well as the otitis media being a complication of measles. Two died of meningitis following mastoid disease, both of them being streptococcic infections. The simple mastoid operation was done in ten of these cases, nine of these operations being made necessary because of mastoiditis with urgent symptoms. The tenth one was a case in which the discharge had persisted in spite of every method of treatment, including the use of vaccines, for more than eight weeks, and the simple mastoid operation was done to cure the otorrhea. The large percentage of mastoid operations in this series is accounted for by the fact that most of these cases complicated measles of a very severe type. It is a common observation that otitis media complicating measles is likely to be severe in some epidemics, and is very prone to cause mastoiditis. This has been our experience. Twenty-five of the cases mentioned above were treated with vaccines. In twenty the vaccines were entirely successful. Ten of these are the cases reported in this paper, the course of the disease and the outcome in the other ten being exactly comparable to the cases reported. In two cases the vaccines were of very doubtful value. These cases finally recovered but there was nothing to show that the vaccines had anything to do with the outcome. One case escaped from observation after having shown marked improvement from one dose of vaccine. In the remaining three cases the vaccines were entirely unsuccessful. In one of these the use of vaccines was not begun until the eighth week of the disease, and although at times some improvement took place, a cure was not effected. In the second the suppurative condition subsided but the functional result was so bad as to make it necessary to discharge the man from the service on account of deafness. The third unsuccessful case was the one mentioned above in which it became necessary to do a simple mastoid operation.

In computing the value of the vaccines in this series of cases it should be kept in mind that the twenty-five cases in which they were used were of a severe type, and most of them had persisted after long continued local treatment. It is quite probable that some of them would have finally subsided under local treatment alone, but it is unlikely that the functional results would have been so good. A considerable number of them, however, would have probably gone on in a chronic state, with all of its accompanying dangers. The aim of everyone who is called upon to treat suppurative diseases of the middle ear should be to cure every acute case instead of allowing it to become chronic. It is safe to say that all cases of acute otitis media which do not end fatally are curable, but that a large percentage are not cured is proven by the number of patients with chronic otitis media that every otologist has under his care.

During the year 1911, six men out of every thousand were rejected for the military service at Columbus Barracks, O., because of chronic suppurative otitis media, this being a larger rejection rate than for any other one disease except mitral regurgitation and gonorrhea. This did not represent the entire number rejected for this cause by any means, for a good percentage had already been rejected at the recruiting stations on account of defective hearing or discharge from the ear, and thus never reached the recruit depot at Columbus Barracks. I have made this statement to show how necessary it is to use every means at our command to effect a cure in every case of acute otitis media. A certain number can be cured by local treatment alone. Then a certain number which do not respond to local measures will clear up when the proper vaccine is used. When all medical means are exhausted there still remain a few cases which are curable only by surgical means. These can be cured by the simple mastoid operation, and it is being insisted upon more and more by otologists everywhere that cases of acute otitis media which cannot be cured by other means should have the simple mastoid operation performed.

From my own, and the experience of others, I think it can now be stated that the use of vaccine treatment in acute suppurative otitis media should be confined to those cases which are resistant to local treatment, and then it should be used in addition to, and not to the exclusion of, such treatment. They are undoubtedly a valuable addition to our present means of treating such cases. In addition to these acute cases it is the general opinion of men who have used them that vaccines are of value in most subacute cases. In chronic cases their field of usefulness is much more restricted, depending probably upon two factors, the amount of necrosis and the condition of the circulation in the mastoid. Enough cases have been reported by different observers to show that vaccines are an aid to the treatment of chronic cases even of long standing, but of course the more chronic the disease becomes the more is it likely that operative measures will be necessary to effect a cure.

Even with the above limitations it must be acknowledged that vaccines have a definite place in the treatment of suppurative conditions of the middle ear. The dangers accompanying chronic otitis media are being recognized now as never before, and if the vaccines will prevent a certain number of cases from becoming chronic, and limit the ravages of the disease in those already chronic, then their use is not only justified but becomes highly imperative.

Columbus Barracks, Columbus, O.

GALLSTONES.*

By HAROLD DEWOLF, M.D.,
THE GLEN SPRINGS, WATKINS, N. Y.

THE subject of gallstones, which has been assigned to me, is too large to approach in any but a very imperfect and incomplete way, if one is to keep within the necessary time limit. I have, therefore, divided my paper into the following customary subheads and will touch briefly on the first few, leaving the greater part of my time for the consideration of diagnosis and treatment. The subheads are (1) occurrence; (2) physical and chemical properties; (3) etiological factors; (4) symptomatology; (5) differential diagnosis; (6) complications, and (7) treatment.

Occurrence: The condition is very rare in India and the East generally, according to many writers, this being due, perhaps, to the fact that it is not always recognized, but probably largely to the habits of dress, eating, and living. In Europe and America, on the other hand, gallstones are very frequently met with, by far the greater number of cases being found in the autopsy room, where, strange to relate, the unfortunate patient has probably arrived with some other and more complex diagnosis pinned onto his vestments. To bear this out Riedel and Kehr made a flat statement that 10 per cent. of all persons on whom an autopsy is performed have stones present in the gall-bladder or passages, or have positive evidence of stones having been there. Mayo Robson is both a little more and a little less conservative, although he arrives at practically the same figures, as he puts the number at from 5 per cent. to 12 per cent. Kehr, in order perhaps not to raise the wrath of the medical profession, is kind enough to tell us that 95 per cent. of the cases in which gallstones are found at autopsy presented no symptoms or physical signs of the disease during life. Let us hope he is right, although it seems to be a great opportunity that the surgeons are missing.

Physical and Chemical Properties: In size they vary from that of fine sand to that of a tennis ball. In shape they may be almost anything, depending upon the number present, location, size and many other influences. Generally, however, a single stone is roughly egg-shaped and the smaller ones are much facetted from contact with their fellows. As to the number there may be a single large stone, or the number may go into the hundreds. To quote Robson again, "there have actually been as many as 2000 removed from a single case." The color, too, varies widely and may be anywhere from a pure white to black, the prevailing tint, however, being yellow or brown. Consistence is usually firm and the stone may be easily broken between the fingers, the fractured surfaces appearing crystalline. There is no set rule in this, though, any more than in other characteristics, because stones as hard as uric acid calculi have been found and again as soft as putty, which they may also resemble in other respects. Cholesterin, always crystalline, is the secretion of mucous membranes generally and forms by far the greater part of the stone, but it is usually built around a clump of desquamated epithelial cells, a mucus plug, or a foreign body, and is always held together by a cement-like substance, formed of mucus, and calcium margarate, stearate and palmiate. The biliary salts, sodium glycocholate and sodium taurocholate and the bile pigments are almost always present, to the latter being due the color of the calculus. As we have said, the important ingredient, cholesterin, is formed not from the bile itself and not in the liver, but from mucous membranes. Consequently, an overstimulated membrane will throw out an excess of cholesterin which requires, therefore, an excess of salts to hold it in solution. Lacking the salts, the other material is promptly precipitated and forms our stone. Another extremely interesting fact is that bile itself being an irritant, will, when allowed to act upon healthy tissue, produce a mild grade of inflammation and promote the outpouring of mucus and cholesterin. It will readily be seen then that any inflammatory process in the region of the gall-bladder, even that caused by simple stagnation of bile, as found in the condition known as "torpid liver," will eventually be sufficient cause for the occurrence of biliary calculi. This, however, anticipates our next sub-heading.

Etiological Factors: Someone has said:- "Given a female of sedentary habits approaching the age of 60 and we have a fertile field for gallstones." This seems to be a good rule to follow, as 25 per cent. of the cases are 60 years or over, and the condition occurs four or five times as frequently in women as in men. That the ladies should have the advantage, or disadvantage, is not surprising when we stop to consider that pregnancy—and 90 per cent. of women with gallstones have borne children—is a great factor in producing chronic constipation and interfering with the proper outflow of bile. Wearing corsets, especially when accompanied by the pernicious habit of hooking from the top down, "will tend to distort the liver and depress the fundus of the gall-bladder" (Allbutt). It seems hardly necessary to mention again the sedentary life as a causative factor, but its importance may perhaps be impressed upon one's mind by repetition and by the hasty enumeration of the all too frequent events following upon this most common complaint. These are loss of tone in the abdominal muscles with consequent removal of accessory forces needed for defecation; the result is constipation. Next the retained irritant matter sets up a catarrhal inflammation, which sooner or later produces paresis of the intestinal musculature, and of the closely related biliary passages, with the subsequent stagnation of bile and increase in the production of cholesterin. But what of the diet? It surely must have an influence, and it does. Great reduction of nitrogenous food, as found in vegetarian Germany, leads directly to precipitation of cholesterin through the insufficient presence of the bile salts to keep it in solution. Indeed, with all their advances in medicine, the Germans still probably lead the list in the number of gallstone cases, while England, with its heavy meat eaters, is far, far behind. Thudicum has made some very interesting observations in this connection among the lower animals, and he tells us that the condition is never found among the carnivora. It has also been frequently noted that the diabetic on his diet high in proteid rarely develops biliary calculi. Perhaps, though, the enormous quantities of fluid that the diabetic indulges in may be preventive and conversely the small water drinker may become a fit subject. If, now, into this fertile ground we have so carefully prepared a few stray bacteria from the well stocked gut should wander, the picture is completed. In this connection one may say that gall-

*Read before the Schuyler County Medical Society, February 20, 1912.

stones very frequently occur in old typhoid cases, and, according to Robson, in those who have had influenza. However, other organisms are also found, notably the colon bacillus, staphylococcus, streptococcus and *Bacillus subtilis*. Probably then this actual infection of the gall-bladder is the exciting agent in all cases of gallstones.

Symptoms: Here, as in most other conditions, there is no set rule or sequence. There may be no symptoms at all, or merely depression of spirits with gastric discomfort. Again we find recurrent attacks of dyspepsia which resist all treatment and eventually lead us to suspect the presence of a pathological lesion other than one local to the stomach. Lilienthal has apparently been particularly struck by the great number of such cases, which pass through the hands of "stomach specialist" after "stomach specialist" only to eventually come to the surgeon during an acute attack of colic. The same observer makes a special plea for early and accurate diagnosis in such cases and asks that the medical man should always consider the possibility of gall-bladder disease and should not delay too long in seeking operative relief. He says in part: "Indigestion with repeated attacks of pain and belching, or even no pain, but severe discomfort, particularly after eating meat, should, in the absence of emaciation and jaundice, arouse a suspicion of gall-bladder stones of large size." The following case, illustrating the conditions described above, is typical of what one so often meets in private practice and shows clearly the errors to which the medical man is prone.

Mrs. S., 53 years of age, was first seen in October, 1911. The chief complaint was of irregular, severe attacks of pain in the region of stomach, the last one having been two months previously. Family history was negative. Previous illnesses included ordinary exanthemata of childhood; acute rheumatic fever and malaria in early adult life; sciatica; a condition diagnosed as peritonitis (probably appendicitis) at the age of 40; and several attacks of "grippe" and tonsillitis. There were no injuries or operations. Menstruation had ceased normally at 50. Patient had had four normal labors. The habits were good except for obstinate constipation of many years' standing, for which the constant use of pills and enemas was necessary.

There was a history of a sudden intense pain in the epigastrium seventeen years before, the attack lasting for twelve hours and being eventually relieved by morphine. There was no nausea, vomiting, or diarrhea, and no icteroid tint to the skin or scleræ as far as was known. During the following nineteen months the attacks recurred at intervals, sometimes accompanied by a chill, nausea, and vomiting, and then for three years the patient was comparatively free, but during the past ten years the symptoms had returned with greater frequency and violence, a single attack, as described by the patient, consisting of rather sudden, deep-seated pain in the region of stomach, radiating to the back and right breast, and accompanied by enormous quantities of gas in both stomach and intestines. The patient thought that the attacks were brought on by excitement, everexertion, or by eating certain articles of food, chicken being the most frequent offender. She had, therefore, eaten little meat for six months and the attacks had been infrequent, the last one having occurred in August, 1911. Physical examination showed a well-nourished white female adult with a clear, normal complexion. Pupils normal. Scleræ injected. Mucous membranes of fair color, tongue coated and pharynx congested. There were dullness, increased tactile and vocal fremitus, bronchovesicular breathing, and a few clicking râles at the right apex. The lungs were otherwise normal. The heart showed a soft systolic murmur in the pulmonary area and the apex sounds were of poor muscular quality. The abdomen was soft and relaxed, with no areas of tenderness and no masses. The liver and spleen were of normal size and there was no tenderness or sense of resistance in the gall-bladder region. The lower pole of the right kidney was palpable. The lesser curvature of the stomach was made out at the fifth interspace; the greater curvature was 2½ inches above the umbilicus, the vertical diameter being 4 inches. With the patient in the standing position the stomach dropped 1½ inches. The systolic blood pressure registered 144, diastolic 92; the pulse pressure being 52. Pulse was 82, regular, small, and of fair strength.

It will be seen that this case showed nothing referable to the gall-bladder, although the character of the attacks was somewhat of the nature of biliary colic. That the condition did not impress itself upon the minds of the patient's many eminent medical advisers as of an operative nature, even though it had existed without improvement for over fifteen years, conclusively proves that Lilienthal's appeal for surgical relief in such cases is justified. This patient was finally operated upon and a single large stone was removed from the gall-bladder.

These atypical cases are undoubtedly of great value to us as medical men, but we are now particularly interested in the more straightforward symptom-complex which is most often seen. Here a sudden knifelike pain in the right hypochondrium, radiating to the back and shoulder of the same side, with nausea, vomiting, and perhaps collapse is practically pathognomonic of an attempt to pass a stone through the gall-passages. Allbutt and Rolleston's "System of Medicine" gives the following seven symptoms and physical signs associated with stone somewhere in the gall-bladder, or ducts:

(1) Parosysmal pain of lancinating character with dull aching between attacks. (2) Vomiting, which may be paroxysmal or continuous and has been fatal. (3) Collapse, during which death may ensue. (4) Jaundice, which may be persistent or intermittent, depending upon whether the stone permanently obstructs the hepatic or common duct or only interferes at times. (5) Malaria-like attacks of irregular chill, fever and sweat (Charcot's hepatic fever), which may be due to irritation, but are more likely the result of absorption of toxic material. (6) Rigidity of the right rectus with presence of a tender spot between the ninth costal cartilage and umbilicus. (7) A tumor or mass representing the gall-bladder itself, this being seldom found in acute cases. Still another means of diagnosis is the presence of stones in the feces after an acute attack of colic. Osler says the following are characteristic of stone in the common duct: "Jaundice of varying intensity, deepening after each attack, paroxysms of chill, fever, and sweat, pains in the liver region, and gastric disturbances." Time will not permit enlargement upon or elaboration of these symptoms so we will pass rapidly on, simply mentioning the more common complications, a few of the conditions confused with gallstones, and then have a word as to treatment.

Complications: These may be local or general.

The local complications are as follows: In the gall-bladder: empyema, gangrene, rupture, perforation, cancer; in the gall-passages: suppurative cholangitis, rupture or perforation, stricture, cancer; in the liver; abscess; in the pancreas; acute, subacute, or chronic pancreatitis, cancer; in the intestines: ileus with enormous distention due to atony, acute obstruction from paralysis, impacted stone, stricture, perforation; in the peritoneal cavity: acute or general peritonitis, subphrenic abscess, etc. The general complications are hemorrhages from long continued jaundice, septicemia, pyemia, and chronic invalidism.

Differential Diagnosis.—The two conditions most commonly found and perhaps most difficult to differentiate from acute gallstone seizures are appendicular and right renal colic. Either one of these may be impossible of accurate diagnosis during the attack, especially if morphine is given, but there are generally a few well marked points of difference. The location of the pain below the tip of the ninth right rib and its radiation toward the right shoulder, together with the possible history of past attacks followed by jaundice, are frequently sufficient to determine the nature of the attack. In lead colic the cramps are general, there is often a lead line on gums, obstinate constipation is present, and a history of the use of lead in some form may be obtained. Malignant growths involving the biliary passages are perhaps most frequently only differentiated at operation, but the deep seated, boring pain, the persistent increasing jaundice, and emaciation often help to distinguish the condition from calculi. I will only mention in passing chronic pancreatitis, duocenal ulcer, angina pectoris, neuralgia, and hysteria, but they must certainly be borne in mind. Dyspepsia with flatulency has already been considered, so I will not discuss it further.

Treatment: This may be medical or surgical, the former being divided again into preventive and palliative. I say palliative advisedly because there is no curative medical treatment for gallstones known today, although it may be possible by proper measures to prevent the further formation of calculi. The preventive treatment may be summed up in a few words as it really is nothing more than leading a perfectly rational existence, something to which, unfortunately, our elderly female patients are strongly averse; a normal amount of outdoor exercise daily; clothing properly made and loosely worn, especial attention being called again to the habit so common among modern women of wearing tight corsets laced or hooked from the top down; a carefully selected mixed diet consisting largely of proteids, fats, and green vegetables, with carbohydrates cut to a minimum, and fluids, especially water, in sufficient quantities; with the ordinary care that any intelligent individual would give to his personal hygiene, would seem to be sufficient to prevent the formation of gallstones. These rules are so sane and simple that it would appear perfectly natural for any patient to follow them, but our experience teaches us that the human being will at times go out of his or her way to lead what is so obviously an abnormal life. Palliative treatment, or medical measures to combat the actual disease, are really very few, although there have been innumerable remedies used and recommended by the enthusiastic experimenters whose ideas we so frequently find expressed at great length in the medical journals. Of these measures for the possible prevention of further acute attacks there is only one that has thus far stood the test of time. I refer to the administration of large doses of olive oil. The rationale of this line of treatment is not quite clear, but Brockbank gives us a very plausible explanation and is worth quoting as follows: "Another explanation of the reported disappearance of gallstones after large doses of oil may be derived from the action of soap and fats on cholesterin. A digested fat passes into the circulation from the alimentary canal in three forms—as unchanged fat, and as the corresponding fatty acid and soap. All occur normally in the bile, and the amount present in the bile increases with the amount of fat taken in the diet. Oil, fatty acids, and soap all dissolve cholesterin readily and break up a gallstone. If, then, the oil, fatty acid, and soap appear in the bile in increased amount after large doses of oil, it is very probable that the gallstone is attacked by them, especially by the soap, and in time dissolved, or so reduced in bulk as to be enabled to pass out into the duodenum."

Abdominal massage, with the object of expressing a stone into the intestine is still I believe highly recommended by some writers, but the consensus of opinion is that this line of treatment is altogether too painful and dangerous, and the possibility of expressing the stone too remote to make it of any value in at least the majority of cases. For the relief of an acute attack the application of hot fomentations to the gall-bladder region, the administration of belladonna with the coal-tar products, or one of the salicylates, and often codein or morphine, are necessary. Last, and often too late, we have recourse to surgery. This, then, is the only curative measure and consists in removal of the stone or stones by operation. The scope of this paper does not include discussion of the various means of attaining this end, but the principle is the same in any case, that is, permanent relief or cure of the condition.

OBSERVATIONS ON VESICAL CALCULI.*

By L. SEXTON, B.S., M.D.

NEW ORLEANS, LA.

Dr. Ben Johnson of Washington, D. C., 1895, by corresponding with four hundred representative surgeons in the South found reported 1,088 cases of vesical calculi, viz., in Alabama, 10; Arkansas, 11; Florida, 28; Georgia, 90; Kentucky, 56; Louisiana, 19; Mississippi, 6; North Carolina, 126; South Carolina, 66; Tennessee, 128; Texas, 98; Virginia, 430. About 1 per cent. of the autopsies at the Charity Hospital in New Orleans show urinary calculi of some kind, negroes to white about one to five.

The number of cases of urinary calculi in the Charity Hospital in twenty years is given by Dr. H. B. Gessner as 158; whites, 124; colored, 34. During twenty-five years of general practice we have had ten cases of urinary calculi. Some of the points of interest in connection with these cases and their rarity is the excuse for this paper.

It was originally thought by the laity that drinking hard water was the cause of stone in the bladder. In Kentucky, Virginia, and Tennessee, limestone regions, where much of the water comes through lime-bearing strata, being saturated with different lime and alkaline salts, vesical calculi were supposed to be more frequent than in communities where soft

*Read at the annual meeting of the Louisiana State Medical Society, New Orleans, 1912.

water was consumed. It would seem reasonable that the larger ingestion of these salts might tend toward the formation of stone in the bladder, but statistics do not bear this out. It must be remembered that these alkaline waters must run the gantlet of an acid stomach and all the secretions in the body so that the urine secreted from the blood has very little to do with the alkalinity of the water consumed.

Again, in Virginia and Tennessee, where the water is hard, and many tropical countries, as India, where cistern or rain water is largely consumed, or where soft well water is used, there seem to be about as many vesical calculi as in the countries where hard water has to be consumed. In our judgment stone in the bladder has more relation to the meat and rich nitrogenous food which we eat and the alcoholic and malt liquors we drink than to the water we use.

Many cases of stone in the bladder are preceded by nephritic colic, in which the uric acid calculi form in the pelvis of the kidney, descend through the ureter into the bladder, where, as the saying goes, "the rolling stone gathers" the phosphates and urates mixed with mucus from the bladder wall and thus enlarges from the small uric acid crystal to the larger bladder stone.

Causes of stone are also constitutional conditions tending toward lithiasis or oxaluria. They are very common in children during the first ten years of life, and in elderly men. They are very rare from ten to twenty-five, the active age, and in women on account of the large size and shortness of the urethra. They are said to be very common in India and Arabia and in all tropical countries where such a large amount of fluid escapes from the body by perspiration that the urine is not sufficient in amount to dissolve or wash them away while they are small.

Uric acid, the nucleus around which so many stones form, may be found in consequence of the eating of nitrogenous food, the taking of alcoholic drinks, imperfect digestion, torpid liver, deficiency of fresh air, lack of exercise, and any increased metabolism, as in violent exercise or in fever. Under such conditions urea is converted into uric acid or its salts. These conditions are quite common in gouty and rheumatic subjects.

Uric acid calculi are the basis of three-fourths of bladder stones. The amorphous phosphate stone usually follows some infection of the urinary tract or septic condition in the bladder. Uric acid or oxalate calculi cause the least irritation to the bladder wall; they begin in the pelvis of the kidney and enlarge very rapidly after their descent into the bladder by the accumulation of phosphates and mucus which they gather with age. They are the principal stones found in the bladder of men past middle life; particularly if they are large drinkers or eaters, or with gouty and rheumatic tendencies. Uric acid sand, or gravel of a reddish color, stains the vessel in which the urine is permitted to stand, and the uric acid calculus is brown in color, dense, usually of smooth or slightly modular surface; on cross-section it shows rings like the trunk of a tree, the outer lamina being usually made up of phosphatic material.

The mulberry calculus, so called on account of its irregular or modular appearance, is very hard and darker in color than the other stones, owing to its admixture with blood. The urate of ammonium calculus resembles the uric acid, but is lighter in color. Any stone or foreign body in the bladder becomes coated with phosphatic deposit, when the urine is alkaline, as in chronic cystitis. The nucleus of a stone may be a blood clot, some foreign body, renal calculus, or inspissated mucus. The laminated portions of the stone are superimposed layers of oxalate of lime, uric acid, urate of ammonium, or phosphates; all the layers are held together by vesical mucus and phosphatic material, a sort of cement by which the stone is built up or made larger. The number of stones may vary from one to one hundred; when there are many stones they are usually small and facetted.

As said before, gouty or rheumatic subjects, patients with uric acid diathesis, or large meat eaters and beer drinkers, patients with cardiovascular and renal complications are the ones most likely to become afflicted with bladder stones. People of sedentary habits are the sort of subjects who seem to secrete the preponderance of urates and phosphates, the principal salts in the composition of bladder stones. The free drinking of water, milk, or fluids of any kind in younger subjects tends to wash out any of these urinary sediments which accumulate in the most dependent portion of the bladder just as they do in the bottom of a vessel. They are washed out by free urination, but in older or strictured subjects in whom the flow of urine or the outpassing of smaller stones is impeded by an enlarged prostate or a stricture there is a predisposition to the formation of stone in the bladder. The enlarged prostate may hinder the diagnosis of the stone by the stone becoming encysted behind the prostate gland in the trigone of the bladder so that the introduction of an ordinary sound may not come in contact with it. It is therefore necessary that, in examining for stones imbedded in this position a stone searcher with a short sharp curve which can be turned back into this pocket should be used.

The common symptoms of stone in the bladder are too well known to require discussion at any great length here. When a stone is present the walls of the bladder are hypertrophied, its mucous membrane may be ulcerated and inflammation may extend up the ureters to the kidneys, producing nephritis. The urine is ammoniacal and very irritating. There is pain in the head of the penis and frequent urination during the day and night, especially after rough exercise, as riding in a wagon or on horseback. The last few drops of urine are stained with blood, there is a nervous feeling when the bladder is entirely empty, dribbling occurs for a time after urination has ceased, there may be a sudden stoppage to the free flow of urine, and blood, mucus, and albumin are not infrequently found in the urine.

We recently had a case presenting the larger portion of these symptoms which had been treated for stricture and enlarged prostate without the stone being detected. Having the history of getting up at night and the sudden stoppage of urination, we made a careful search, when we discovered the distinct click of the stone on the first examination. A large stone was successfully removed by a suprapubic operation. It is therefore necessary when any of these common bladder symptoms are present to go minutely into the examination with the *x*-ray, a cystoscope, or a stone searcher until we are sure that no calculus is present; as it is rather embarrassing after long treatment for cystitis, enlarged prostate, or some other bladder trouble to have another surgeon find and extract a stone.

Just a word about the method for operation before closing.

Lithotrity is the operation of choice when the stones are under two inches in their long diameter, and are composed of phosphates and urates. The suprapubic operation is to be preferred if the prostate gland is enlarged, if the stone is too hard to crush, when there are multiple and sacculated stones, when cystitis renders it necessary to drain the bladder. We are personally more familiar with and prefer suprapubic operation in which one can actually see the parts instead of working through the perineum in the dark. There should be from four to six ounces of fluid in the bladder when the lithotrite is introduced. The urethra should be dilated as large as possible in order to admit a good-sized instrument, the lithotrite should be kept open after it enters the bladder, as the stone may fall into its grasp at any time, when it can be easily crushed by tightening the screw on the end of the instrument; the blades should be well fenestrated in order to hold and crush the stone when the latter is grasped. A large evacuating catheter should be introduced after the lithotrite has been removed; the evacuator should be filled with boracic acid solution and pumped into and out of the bladder until all fragments have been removed. It becomes necessary to reintroduce the lithotrite in some cases in order to crush the larger fragments of the stone.

The contraindications for litholapaxy have been given as encysted calculus, a stone two inches in diameter, an oxalate of calcium stone which it is impossible to crush, urethral stricture, large prostate, a sacculated or contracted bladder.

Median lithotomy is the operation of choice by some surgeons when cystitis and enlarged prostate are present, requiring removal of the latter and draining. The suprapubic operation is contraindicated in a small contracted septic bladder with diseased walls. Any incision through the perineum is more or less damaging to the sexual function and this, even in old subjects, should be carefully guarded. There are some cases in which an enlarged prostate may be removed together with the stone through the median perineal incision, but in the vast majority of cases the suprapubic incision leaves the parts in better condition and the bladder with less traumatism and the sexual function, if any remains, undisturbed. The prostate is also easily removed through this incision.

In suprapubic operations hemorrhage is much less likely and if drainage is necessary it can be accomplished through a catheter, though not so well as through the perineal route. In some of the cases where there is not any violent cystitis or bladder infection it is possible to close the walls after all the débris has been removed by a Lembert-Czerny suture through muscular coat closing the incision in the bladder just as in any other wounded viscus. It is hardly necessary to remark that bladder asepsis obtained through irrigation with boracic acid should precede any surgical operation on the organ.

The treatment should not stop with removing the stone; a prohibition of malt and alcoholic drinks and nitrogenous food, the free use of alkaline waters, and an abundance of exercise and fresh air should constitute the after-treatment of an operation for stone in the bladder.

In the cases in which the stones (shown at the meeting of the Society) were removed we distended the bladder with ten ounces of boracic acid solution, applied a rubber band around the penis, and inserted a rectal bag or tampon above the sphincter ani. We then made a three-inch longitudinal incision in the hypogastric region ending just over the symphysis pubis; this opened down upon the prevesical connective tissue which we divided, pushing up the peritoneum. We caught the bladder with forceps, inserted two suspension sutures, then divided the bladder wall in the median line, catching the edges of the bladder with forceps on either side. Inserting the index finger, we found the stone in the trigone of the bladder, removing it with the fingers. We irrigated the organ with warm boric acid solution, removing all débris and mucus. We then closed the incision in the bladder wall by Lembert-Czerny sutures, and adjusted the muscles and skin, draining the bladder through a catheter to which was attached a long tube leading to a basin under the bed and the wound by a small gauze drain in its most dependent portion. All the patients made a speedy and uninterrupted recovery.

INTESTINAL OBSTRUCTION, WITH REPORT OF CASES.

By C. P. FARNSWORTH, M.D.,

CHAMBERLAIN, S. D.

Intestinal obstruction, especially the acute form, is one of the most formidable difficulties with which the surgeon is confronted. Appendicitis and its treatment is simple compared with intestinal obstruction. The appendix is easily located and the immense amount of literature concerning the procedures makes it certain as to what should be done. When a case of intestinal obstruction presents itself with a distended abdomen and a rapid pulse and subnormal temperature, the patient being in an almost moribund condition, one wishes in his heart that he were a humble day laborer and that the surgical clearing houses which receive the nice, clean cases and can reject the questionable ones, had these as well. But such cannot be and something must be done at once or our patient will be in his long home before his appointed time.

The treatment of acute obstruction has its difficulties. The older generation of practitioners relied on starvation, opium, and rest—and divine interposition. Some resorted to drastic cathartics and, sad to relate, some still insist on that form of treatment. Modern surgery does not wait for the patient to get well of his own accord if it can persuade either the patient or his family to resort at once to a scientific instead of an empirical procedure.

The evidences of obstruction are absence of fecal discharge, absolute or partial, for the obstruction may not be complete; distention of the abdomen; and pain either at the point of obstruction or more often in the stomach, accompanied by retching and vomiting, the latter being at first usually of a mucobilious nature, but as the gravity of the case increases becoming stercoraceous. The patient finally enters a stage of shock with rapid pulse, subnormal temperature, and distended abdomen if the obstruction is low down; in cases where it is high up the distention may not be great, but there are evidences of severe toxemia.

Purgatives should be strictly avoided in all cases as they only serve to increase the pain and make the obstruction more serious while they do not relieve the condition. Food, likewise, should be withheld from both mouth and rectum. There is little absorption except of fluids in rectal feeding, even when the intestine is normal; when it is congested and distressed there is still less. The fluids of the body may be kept up by proctoclysis or hypodermoclysis, but no other attempt need be made of a nutri-

tional nature. Enemata should be administered, but if after the lower bowel has been washed out several times the fluid comes back unchanged and at the same time the vomiting or pain or distention continues, no relief can be hoped for other than by operation. Delay is dangerous because it lessens the chances for recovery. We should not wait for fecal vomiting but proceed at once to operate. The fatal cases following operation are not due to the operation, but to the delay and to the grave changes in the bowel caused by the long continued obstruction and devitalization of the tissues from the retention of toxins and the distention. This is especially true in those cases in which the obstruction is high up so that partial movements follow the first enema, the patient consequently not believing the physician. In these cases it is well to refuse to attend the case unless the patient consents to surgical interference. Otherwise there is practically no chance of recovery.

The stomach should be washed and the patient should be quickly prepared for laparotomy by shaving the abdomen and painting it with a solution of iodine. The incision, except in cases of appendicitis and hernia, should be made in the median line below the umbilicus and long enough to admit the whole hand. When the peritoneal cavity has been opened and all hemorrhage has been arrested the hand is introduced into the abdomen and the rectum and cecum are examined. In case there is no obstruction here or in the ileum, collapsed coils of intestine should be sought for. These are generally found in the pelvis. If found, they should be run through the fingers quickly till the point of obstruction is reached. Sterile pads of gauze wrung out of hot salt solution should be so placed as to prevent the intestines from escaping from the abdomen. If they cannot be kept in the peritoneal cavity the most distended portion should have the contents drawn off with an Ochsner trocar or incised and the contents allowed to escape. The opening in the bowel should be closed with a Czerny-Lembert suture. When the obstruction is located it must be treated according to the conditions found. The following is a series of cases coming under my care with the procedure in each case:

Case I.—Mr. G., referred to me by Dr. Frederick Treon of Chamberlain, had pain in the abdomen with persistent vomiting of biliary matter. Enemata brought fair bowel movements and lavage relieved the vomiting for a time. The pain continued and the vomiting returned. Enemata gave small movements but the patient was not relieved. We advised operation, but the patient refused for nearly a week. Finally an operation was allowed, but the patient was then almost moribund. The exploring hand showed an obstruction from an internal hernia about 18 inches from the pylorus. The bowel was gangrenous and the gangrenous portion was excised and an end-to-end anastomosis was performed with the Connell suture. The patient died the next day.

Case II.—Mr. D., an old soldier, had had considerable pain occasionally in the left iliac fossa similar to that of appendicitis. This time there was complete obstruction with great pain and vomiting. An immediate operation was advised and accepted. The patient was quickly prepared and the median incision made. The exploring hand traced the collapsed bowel to the left hypochondriac region, where an adherent Meckel's diverticulum was encountered. It was dissected loose and brought up into the wound and excised and the bowel was closed by through-and-through sutures of chromicized catgut. Four hours after the operation the patient had a large bowel movement. A complete and uneventful recovery took place.

Case III.—Mrs. B. was referred to me by Dr. James Miller of Winner, S. D., for pus-tube. The operation for pus-tube was successfully performed, but the tenth day after the operation the patient developed symptoms of obstruction; operation was advised, but the patient demurred. The family was sent for. They naturally were somewhat adverse to operating, but I insisted. A second laparotomy disclosed a knuckle of the ileum attached by an inflammatory process to the posterior abdominal wall over the left sacroiliac synchondrosis. The involvement was so extensive and dense that it was determined to do a side-to-side anastomosis without disturbing the inflamed area. This was done after evacuating the proximal bowel by means of the Ochsner trocar and closing the trocar wound by a purse-string suture. The anastomosis was done with a Connell suture. The recovery was uneventful and the patient was discharged at the end of three weeks and has remained well ever since.

Case IV.—Master N., a child of 10 years, with an acute intestinal obstruction of eleven days' standing. The patient's pulse was 150 to 160; the temperature 95° F. The abdomen was distended to its fullest capacity. The facies was that of rapidly approaching dissolution. The abdomen was opened to the left of the median line and the first loop of bowel which presented itself was brought up and nicked and the contents disposed of in a pus-basin which was filled many times. The opening in the bowel was sutured into the abdominal wound with as little handling of the bowel as was possible. A normal saline infusion was administered and strychnine in 1/60 grain doses given hypodermically every four hours. The patient slowly recovered. Six weeks afterwards a second laparotomy was done and the appendix was found to have a large enterolith in it and was bound down to the posterior abdominal wall in such a way that the ileum was completely closed by the adhesions from the appendix wrapped around it. The appendix was removed, and what we now know to have been a Lane's kink was dissected off and the bowel relieved from adhesions. The artificial anus was closed and the opening in the bowel repaired, when it was found that the lumen was too small. A side-to-side anastomosis was then performed and the abdomen closed. An uninterrupted recovery ensued.

Case V.—Miss S., referred to me by Dr. Wiley of Kimball. Patient had complete obstruction for twenty-six hours from an irreducible strangulated right femoral hernia. An immediate operation was advised. The abdomen was shaved and solution of iodine applied. A curved incision was made above the tumor and on opening the hernial sac a large amount of turbid bloody fluid escaped and disclosed the dark-colored gangrenous bowel. A median abdominal incision was made and the incarcerated bowel was isolated by hot gauze pads. The bowel was delivered and a section of six inches of gangrenous bowel excised. The ends of the bowel were ligated and invaginated by a purse-string suture and a side-to-side anastomosis was performed. The hernial sac was cleansed, ligated, and inverted, and the external femoral ring was closed. The abdomen was closed and recovery ensued.

Case VI.—Mr. D., an elderly man with an old hernia, came to me suffering with an irreducible strangulated hernia, which caused a complete obstruction. The patient was prepared and was on the operating table within a half hour after coming to the sanatorium. A curved incision above the tumor was made and the sac, on being opened, discharged a large quantity of serosanguineous fluid. The constriction was sought and nicked, and the bowel and the included mesentery were treated with hot laparotomy pads till the pinkish color indicated that the bowel was not destroyed. An exploration of the bowel below the sac disclosed a constricting band of adhesions within the abdominal cavity. These were dissected loose. The hernial sac was dissected loose from the cord and also from the internal ring and ligated about two inches out from the internal ring, the sac was inverted and the superficial fascia retracted strongly, and the top or the end of the sac was caught with a round needle passed through the abdominal wall and the sac was securely anchored. This procedure is an additional safeguard against recurrence of the inguinal hernia, as it makes a double layer of peritoneum over the internal ring from the internal abdominal aspect. The canal was closed by the Bassini method. An uninterrupted recovery ensued, the patient leaving for home on the seventeenth day.

Case VII.—Mr. C., a young man referred to me by Dr. F. Treon of Chamberlin, S. D. Patient had been treated about ten days before for a recent strangulated hernia. The strangulated condition had returned and the patient was in intense agony, vomiting and retching. Morphine had been injected, so he was anesthetized, and on failing to reduce the hernia by taxis an operation was advised and a brother, who accompanied him, gave consent. A curved incision above the tumor was made and the sac was opened. A quantity of straw-colored fluid escaped and a very much inflamed bowel was exposed. The constricting bands were nicked, the bowel was treated and the abdomen explored for any constrictions; the appendix was examined and found full of concretions. The incarcerated bowel was returned and the sac and cord were treated as in Case VI. A split-muscle incision was made over the appendix as the mesoappendix was too short to permit the performance of an appendectomy through the hernial opening. I believe it is very important to make an intraabdominal examination when operating in every case of hernia. The appendix was removed, and the stump was ligated and inverted by a purse-string suture. The patient made a splendid recovery.

Case VIII.—Mrs. C. had an intestinal obstruction of three weeks' standing. I called Dr. S. M. Duncan of Chamberlain to see the patient with me. Dr. Wagar of Bijou Hills had attended the case and had had no results from high colonic flushing. I thought that the obstruction must be low down in the bowel, since the patient who had been quite strong was rapidly becoming weak. If the obstruction is high up the symptoms are very much more severe than with a low obstruction. The patient averred she had had no movement for over three weeks. An incision was made in the median line and the sigmoid sought; a tumor was found in it which proved to be a carcinoma completely occluding the lumen of the bowel. The colon and the whole small intestine were loaded with fecal matter. As the patient seemed quite strong the carcinoma was resected and the ends of the bowels were stitched over and invaginated by a purse-string suture, and then a Lembert suture was made with linen and a left inguinal colostomy was performed after the method of Mayo. That night an immense bowel movement was obtained through the colostomy opening and two were obtained on each of the following days. A large amount was also obtained by irrigating the bowel through the colostomy wound. Supporting treatment was given with hypodermoclysis every four hours, but the patient died on the fifth day from exhaustion and toxemia.

This series of eight cases convinced me that an obstruction should be operated on within the first twenty-four hours or as soon as it is evident. Temporizing and hoping and waiting for nature's cure is a relic of the days of miracles when medical science was ignored and the patients were treated by empirical methods. The use of practical surgical measures is the only safe way and should be done early and not, as usual, as a forlorn hope.

Chamberlain Sanitarium.

Lupus Vulgaris and Scrofuloderma Treated by the Pfannenstill Method.—J. H. Sequeira reports the case of a poorly developed girl, aged sixteen, whose father was healthy, but whose mother suffered from phthisis. The girl had always been delicate. She had pneumonia when young, and had had measles fifteen months ago. The lupus started upon the back of each wrist eight years ago, and the lesions had been scraped. They gradually spread after the operation, and eventually reached the elbow and the upper arm. A little later the face was affected. Fifteen months ago she had what was described as being a tuberculous abscess behind the left ear. This was opened. Her hearing became affected, and she was very deaf. Her voice was husky. She came to the London Hospital in January, 1912, with extensive lupus of the nasal cavity and of the pharynx and palate. There was also double epiphora. There was extensive lupus, with some central scarring upon the hands and forearms up to the elbow. In February, 1912, the back of the right hand became much swollen and edematous and a localized purplish-red swelling developed over the back of the right wrist. This was 2 inches in its long diameter and 1½ inches transversely. The swelling evidently fluctuated, and it was opened, and a thin yellowish pus was evacuated. Later a small oval swelling formed along the line of the lymphatics. On February 21 she was admitted to the ward, and the arm was put on a splint. The ulcerated areas in the nose were treated by packing with gauze, which was kept constantly moistened with a solution of peroxide of hydrogen 10 vols. At the same time she was given 30 grains of sodium iodide *per diem* in divided doses. The tampons soaked with the peroxide were kept constantly in position, except when the patient was asleep. Finding so much improvement of the intranasal condition in this as in numerous other cases treated by the Pfannenstill method, the author had the ulcerated areas upon the forearm and wrist dressed in similar fashion, with great benefit. The case illustrated the value of the method, particularly in the treatment of ulcerative lupus of the cavities. The patient had borne the iodide very well, and to make sure that the condition was not complicated by congenital syphilis a Wassermann reaction was performed, with negative result. The patient has gained 7 pounds while in the hospital, and her general health has improved greatly—*Proceedings of the Royal Society of Medicine.*

Deafness Caused by Excessive Tea Drinking.—A. Sharp reports the case of a woman, aged forty, who complained of increasing deafness for about eighteen months. On examination there was found difficulty in locating sound, but no tinnitus; watch and whispered voice were heard about 6 inches from both ears; nose and throat were healthy; tympanic membranes were normal. Tuning fork tests were typical of nerve deafness. Family history was negative. No syphilis. Patient was subject to worry. She found that strong tea cheered her up, and admitted taking it as often as eight or ten times a day. The tea drinking was stopped, and in four weeks the hearing improved to 18 inches for watch and whispered voice. Improvement continued until the hearing was nearly normal. In spite of warning the patient again took to tea drinking and deafness resulted. On again giving up the habit normal hearing returned.—*Proceedings of the Royal Society of Medicine.*

New York, September 28, 1912.

THE CONGRESS ON HYGIENE AND DEMOGRAPHY.

No more distinguished assembly ever gathered in this nation's capital than that which met the past week to discuss the great problems of personal and racial hygiene. Most of the subjects on the scientific program had already been presented in the various special journals. Nevertheless the purpose of this congress has been admirably accomplished in bringing into definite focus the latest tendencies in preventive medicine and statistical science. One of the conspicuous results of the preceding congress, held in Berlin five years ago, was the fact that it forced upon the attention of several governments the need of efficient legislation pertaining to industrial hygiene. There is reason to anticipate that even to a greater extent the nations of the world will be impressed by the message of the present congress. No more auspicious time than the present could have been chosen for the proclamation of authority upon such subjects as the plague, cholera, poliomyelitis, child welfare, eugenics, and military and naval hygiene.

It is noteworthy that this epoch-making gathering was really a collection of miniature congresses. What more brilliant galaxy for the discussion of tropical hygiene could have been brought together than Celli, Sergent, Brieger, Mesnil, Novy, Chantemesse, and Nicolle? Those who have been in the forefront in attacking the problems of poliomyelitis were almost all present: Landsteiner, Levaditi, Harbitz, Flexner, Römer, Netter, Petersson, and others. Similarly with other subjects. The directory of the congress looked like a miniature edition of "Die Gelehrte Welt." Another striking aspect of this congress was the extraordinary scope of the discussions which ranged all the way from the control of rabies to the hygiene of the engine-room; from the education of immigrants to the training of health officers; from the causes of mortality in the professions to the statistics of appendicitis in the German navy.

Most conspicuous of all in the affairs of the congress was the sympathetic interest in its organization which has been displayed by the Government of the United States and by its President. It is to this interest and to the care with which the organizers planned the congress that must be attributed its extraordinary success. The medical profession of this country will heartily endorse President Taft's advocacy of increasing the scope and usefulness of the Public Health Service. Truly, in the giant strides of modern sanitation one perceives a growing alliance between it and the State, for in the larger problems of colonization, of engineering, of industry, of commerce, and above all, of human welfare, the counsel of the physician must ultimately be sought.

THE FORCIBLE FEEDING OF SUFFRAGE PRISONERS IN ENGLAND.

A STORY whose recital sounds like a chapter from the annals of Torquemada, but in which one may be tempted to perceive a note of retaliation against the English government for the recent infliction of the National Insurance Law, is set forth in a preliminary report in the *Lancet*, August 24, 1912, by Agnes F. Savill, C. W. Mansell Moullin, and Sir Victor Horsley. This report, which seeks to answer the statement of the Home Secretary that the practice of forcible feeding is unattended by danger or pain, is based upon the written statements of 102 of the suffrage prisoners, of whom 90 were subjected to the operation of forcible feeding, as well as upon the examination of many of these prisoners after their release. It is pointed out that the suffrage prisoners have not hunger-struck in order to shorten their sentences, but only to obtain equality of prison treatment for prisoners convicted of like offences, and for justice in observance by the prison officers of the prison rules. The partial success of the "strike" is indicated by the fact that of the 102 prisoners who joined in this stoic protest 46 were released long before the termination of their sentences because of an alarming impairment of health. The above report in its apparent exaggeration of some of the unpleasant consequences of forced feeding has already elicited many vigorous protests from those who had anything to do with this method of penal administration.

An important item in the arraignment of the Government's method of feeding its belligerent and striking suffragettes is the statement that forcible feeding, even when no resistance is offered by the victim, cannot be performed without risk of mechanical injury to the nose and throat. Then follows an enumeration of the actual injuries that have been recorded: laceration of the nasal mucosa, with severe and recurrent bleeding; the production of an abscess in the nose with severe pain over the frontal region; swelling of the mucous membrane of the nose and pharynx, with pain over the area of distribution of the trigeminal nerve; septic pharyngitis; injuries of the lips, cheeks, and gums; the passage of the esophageal tube into the larynx, and the injection of food into the lung. In a large number of cases violent cardiac palpitation followed the forcible feeding, while giddiness, faintness, and collapse were frequent symptoms. In many cases the officials "*rapidly* poured large quantities of often *cold* liquid" into the inhospitable stomachs of the militant martyrs of womanhood suffrage. In many of the cases vomiting was a necessary consequence, and in most instances the sudden distention of the

stomach caused pain, heartburn, and nausea. The general inanition attending this form of tube feeding formed a contrast to the results of this procedure when used as a form of medical treatment in asylum and hospital practice.

It is stated that the most serious effects of the treatment by forcible feeding fall upon the nervous system. In this connection the words of the report may be quoted: "We are not here concerned to discuss the right or wrong of the political methods of the militant suffragist. We merely point out that on admission the prisoners are in a normal mental condition, which cannot be said of the patients who refuse food in the asylums. . . . In the evidence we have personally examined, and in the certificates afforded us by other physicians, there is certainly no evidence of 'hysteria'—using that much-abused word in the sense of exaggerated or excessive display of emotion." The symptoms that supervened upon the release from prison were chiefly those of acute neurasthenia: inability to concentrate the attention, loss of memory, hypersensitiveness to sounds, great fatigue, and general muscular weakness. In other cases the predominant symptoms were weak pulse, dyspepsia, pruritus, and vasomotor instability. As regards the mental condition during their stay in prison it is stated that "to the physical torture of forcible feeding the prison officials in many cases added the intellectual torture of solitary confinement, and to this was added the mental anguish caused by hearing the cries, choking, and struggles of their friends."

An interesting but grewsome chapter in penology is revealed in this report. Certainly the picture has been painted in lurid colors. Yet Bernard Shaw believes that if the suffragettes persist in their refusal to eat the Government should permit them to starve. The ladies will have their own way, anyhow.

MALIGNANT DISEASE OF THE LUNG.

The difficulties surrounding the diagnosis of pulmonary malignant disease, and the fact that this condition is usually mistaken for pulmonary tuberculosis, pleural effusion, or aneurysm, impart considerable interest to the review of this subject presented by A. A. Stevens in the *American Journal of the Medical Sciences,* August, 1912. It is pointed out that secondary malignant disease of the lung or pleura is not uncommon, arising by metastasis from distant organs, or by direct extension from neighboring structures; on the other hand, primary malignant disease of the lung is rare. The statistics of the Breslau Pathological Institute are cited: Of 9,246 autopsies, in which there were 1,000 cases of malignant disease, Pässler found 16 cases of primary carcinoma and 4 cases of primary sarcoma of the lung. Other observers have found primary sarcoma more common than primary carcinoma. As a rule primary sarcoma is limited to one lung, forming a large, infiltrating mass of variable consistency, and of a grayish color, often mottled with hemorrhagic areas. Remote metastases are rare in this condition, but in primary carcinoma secondary growths are found with great frequency in the various abdominal organs and in the muscles.

The chief symptoms of malignant disease of the lung may be those of a progressive consolidation of the lung, of stenosis of the larger bronchi or trachea, or of pleurisy with effusion. There are present dyspnea and cough, which is especially marked when the larger bronchi are involved, or the mediastinum is invaded and the trachea is compressed. In the majority of cases there occurs expectoration; there may be a "currant-jelly" or "prune-juice" sputum, which, however, is not characteristic; there may be fetid expectoration, and there may even appear in the sputum fragments of tissue which under the microscope may reveal the nature of the growth. In most cases hemoptysis is present. Pain is inconstant, but is quite severe when the pleura is involved or the thoracic nerves are compressed. Enlargement of the supraclavicular and axillary glands is an important symptom in carcinoma, but is exceptional in sarcoma. The cachexia that ultimately develops in most cases of malignant disease of the lung is of importance in differentiating this condition from aneurysm, the diagnosis of which is often extremely obscure.

The physical signs of malignant pulmonary disease, in the absence of pleural effusion, are an irregular area of dullness, and if the bronchi in the affected region are pervious, bronchial breathing and bronchophony. In the majority of cases the occlusion of the bronchi gives rise to enfeeblement or suppression of the breath and voice sounds. There may be bulging of the chest wall over the tumor, and in advanced cases the heart and abdominal organs may be displaced. The symptoms of pleurisy with effusion may dominate the clinical picture; the fluid removed by paracentesis is usually bloody, and examination of its sediment may reveal a large number of cells, which, if exhibiting numerous mitoses and asymmetrical division, favor the diagnosis of malignancy.

This diagnosis is often a matter of great difficulty. The presence of malignant disease in another part of the body furnishes an important clue which, however, is apt to fail in the case of primary sarcoma of the lung. Scraps of tissue in the sputum furnish conclusive evidence. In the case of consolidation of the lung suspicion may be aroused by the unusual location or distribution of the dull areas and the constant presence of blood in the sputum without tubercle bacilli. Of great significance are those physical signs that point to stenosis of the air passages, which condition in tumors developing within the lung does not occur, as a rule, until the disease is far advanced. Other conditions that simulate malignant disease are pulmonary syphiloma, and echinococcus disease, or dermoid cyst of the lung. The only characteristic sign of echinococcus disease, apart from the presence of cysts elsewhere, is the expectoration of hydatid membrane, but the presence of a pronounced eosinophilia and the complement fixation test may afford presumptive evidence of the presence of this condition. The coughing up of hair is the only pathognomonic symptom of intrathoracic dermoid cyst. A mediastinal tumor may also simulate cancer of the lung.

THE EFFECT OF CERTAIN CARDIAC REMEDIES ON ARTERIAL PRESSURE.

Of late years the literature dealing with arterial pressure has been profuse, and in many respects traditional views as to heart action have been revolutionized. It is only within recent years that the discovery has been made. Very little is really known concerning the heart. In the *Medical Press and Circular,* August 21, 1912, there is a paper by James Burnet, of Edinburgh, on the effect of certain cardiac remedies on the arterial pressure from the clinical standpoint. The results of his experiments with digitalis showed that even from the outset of its exhibition digitalis had no effect whatever upon the arterial pressure. The action of digitalis as a diuretic cannot, therefore, be explained as due to a rise in blood pressure. This action must be entirely attributed to improvement in the general circulation, so that any venous stasis in the kidney is relieved and the arterial blood pressure to that organ is reestablished. This probably explains why digitalis never produces diuresis in individuals with a normal and healthy circulating apparatus. The experiments with regard to caffeine were interesting, for the author experimenting on himself found that three grains of the citrate produced no change. With five grains a rise was observed which amounted to only 5 mm. of mercury. This, however, might be almost discarded. Within a quarter of an hour the pressure, which was 120 mm. to start with, rose to 130, and in half-an-hour to 135 mm. The headache from which the investigator was suffering was definitely increased. Not until an hour and ten minutes after the drug had been taken did the pressure return to normal. On another occasion ten grains were taken. In ten minutes there was a rise of 15 mm. in the blood pressure, and in half-an-hour 140 mm. was reached. Only in two hours afterwards was a normal reading obtained. Considerable inconvenience was experienced from the resulting diuresis. Caffeine is often recommended as a remedy in cases of migraine, but Burnet is confident that its use is really far from beneficial and actually aggravates the condition by raising the blood pressure in the cerebrum.

It is noted that strychnine is a most valuable stimulant to the circulation in cases in which the latter threatens to fail, as in pneumonia. Its effects on arterial pressure are very definite, and the opinion is expressed that when the blood pressure has fallen below the normal strychnine is the drug to administer. The belief is expressed that the more we know of the real action of drugs the more limited will be the number of those we employ. Assuredly the effect of drugs on the arterial pressure is a matter of great moment, and if Burnet's observations are confirmed it is probable that much of the older teaching on the subject will be set aside.

The Present Status of Casein-Milk.

Three years have elapsed since Finkelstein and Meyer introduced their method of treating acute and chronic gastrointestinal disturbances in infants by means of "casein-milk," which consists of a watery-suspension of freshly prepared casein mixed with an equal quantity of buttermilk. This method, which appeared to be in direct variance with established teachings, is based upon the theory that the harmful factors in cases of alimentary intoxication in infancy are the carbohydrate and mineral constituents of the milk. At first this theory was received by the pediatric world with considerable scepticism, but this has gradually vanished in the face of the brilliant results which have been achieved by those who have tested this novel method of treatment. In Germany Birk, Bahrdt, Welde, Grosser, Benfey, Beck, and others have testified to the value of casein-milk, while in this country its virtues have been recognized by Chapin, Leopold, Dennett, Heiman, Pisek, and many others who have given it a fair trial. An enthusiastic advocate of casein-milk feeding is Professor J. Cassel of Berlin, who in the *Archiv für Kinderheilkunde,* August 13, 1912, details the results he has obtained with this method in 61 cases. These consisted of cases of acute and of subacute dyspepsia, of gastroenteritis of a pronounced toxic type from the very beginning, and of chronic dyspepsia. As the result of his experience Cassel subscribes to the statement of Finkelstein and Meyer that there is no method of infant feeding that cures even severe cases of the above conditions with as much certainty and as quickly as casein-milk. But he finds that it is not necessary to continue this food for such long periods of four to eight weeks as originally recommended. The expense item is an important consideration which is practically prohibitive in the case of the poor families among which these cases are almost wholly found, and even children's hospitals with a limited endowment feel the financial burden which the wide use of casein-milk entails. Nevertheless the fact that in many cases the use of this milk is necessary only for from a few days to one or two weeks, makes the matter of expense one which can be practically disregarded, particularly in view of the ultimate saving resulting from the rapid recovery of the patient fed upon casein-milk. It is to be hoped that this preparation will find a wider use in general practice. Possibly the municipal milk stations might be induced to supply this preparation, just as the milk laboratories have already done. A dried form of casein-milk is now on the market.

News of the Week.

International Congress for the Study of Infantile Hygiene and Pathology.—The next International Congress for the Study of Infantile Hygiene and Pathology will be held at Paris, October 7, 1912. It is the desire of those having charge of the congress that as many pediatrists as possible of foreign countries may attend. The honorary president of the congress is the minister of public instruction of France.

Middleton Goldsmith Lecture.—Dr. E. F. Bashford, Director of the Imperial Cancer Research Fund of London, England, will deliver the Middleton Goldsmith Lecture of the New York Pathological Society on Wednesday and Friday evenings, October 2 and 4, at 8:30, at the New York Academy of Medicine, 17 West 43d Street. Dr. Bashford will speak on "A Review of Recent Cancer Research." The lectures are open to the public, and a cordial invitation to be present is extended to all those interested.

New Hospital.—The completion of the Italian Hospital, which stands at 83d Street and the East

River, New York, was celebrated on September 20 with suitable exercises. Patients will be admitted on October 15. The building, toward the cost of which the Italian Government gave $60,000, will accommodate one hundred patients, and is a five-story steel and stone structure overlooking the river.

Civil Service Examination.—The United States Civil Service Commission announces an open competitive examination for the position of assistant in experimental therapeutics in the Philippine Service, for men only. There is at present a vacancy in the Bureau of Science, Manila, at a salary of $2,000 per year. Applicants desiring to enter the competition should apply at once to the United States Civil Service Commission, Washington, D. C., for Form B. I. A. 2. The examination is open only to male citizens of the United States between the ages of eighteen and forty, who are graduates in medicine and have had at least one year in addition of postgraduate laboratory research work.

Death Rate in New York.—For the week ending September 14, 1912, the death rate in New York City was 12.62 per thousand of population, with a total of 1,251 deaths, while the rate for the same week of 1911 was 12.65. During the week there were 314 deaths under one year of age and 400 under five years. For the thirty-seven weeks of 1912 so far elapsed the death rate per thousand was 14.51, as compared with 15.72 for the same period of 1911.

Death of Centenarian.—Daisy Paul, believed to be 107 years old and the oldest Indian in Canada, died recently on the St. Mary's Indian Reservation, New Brunswick.

Smallpox in Pennsylvania.—The State Commissioner of Health of Pennsylvania after investigating the cases of smallpox at Pittsburgh and at Carbondale recently, has reached the conclusion that the outbreak may be attributed to the failure of physicians and parents to carry out the laws of the State in regard to vaccination. In Pittsburg alone there had been up to September 17, sixteen deaths of unvaccinated children under seven years of age. On that date there were throughout the State 130 cases of the disease. The source of the infection in Pittsburg has not been traced, the first cases discovered there having been in the crowded tenement districts. The Carbondale outbreak, however, is believed to be traceable to a case from New York State, the spread of the disease being due to a wrong diagnosis. The cases were at first thought to be chickenpox and quarantine was considered unnecessary.

State-Wide Campaign.—With the meeting of the officers of the New York State Department of Health and of certain charity aid associations on September 17, in Albany, the fight against tuberculosis in this State received fresh impetus. Already twenty-one counties in the State have decided to build tuberculosis hospitals, and it is expected that nine others will soon do so. In Westchester County, where $250,000 has been appropriated for a hospital, some opposition has arisen to the site selected—a farm of 277 acres situated near Croton Lake, and in the midst of the watershed supplying New York City. Property owners in the neighborhood have also objected on the ground that the establishment of such a hospital will decrease the value of their holdings.

Brain of Dr. McGee.—Dr. E. A. Spitzka has reported that the brain of Dr. McGee, which was delivered to him, weighed 1,410 grams. In a list of 100 eminent men prepared by Dr. Spitzka the average weight of the brain was 1,469.65, that of Ivan Turgenieff, the Russian novelist, ranking first with a weight of 2,012 grams.

Open Air Schools.—With the opening of the fall school term this year over 200 open air schools and fresh air classes will be in operation all over the United States. The first such school was established in Providence, R. I., in January, 1907; on January 1, 1910, there were only thirteen open air schools in the United States, and a year later only twenty-nine, so that the chief increase has been within a very short time. In Massachusetts there are now eighty-six fresh air schools and classes, Boston alone having over eighty; in New York State, twenty-nine, and in Ohio, twenty-one.

Horse Plague.—Twenty thousand horses, it is reported, have already fallen victims in Kansas and Nebraska to the new scourge, the so-called spinal meningitis. The United States Department of Agriculture has sent twenty experts to the affected districts to study and if possible control the epidemic, which is prevalent in seventy-five of the 105 counties of Kansas.

Destroy Infected Cattle.—Seventy-five head of cattle, all infected with tuberculosis, were ordered killed recently by Dr. W. H. Lowe, inspector of the First District of New Jersey. This is the largest single condemnation of diseased cattle yet made in the State, and is the result of the discovery several months ago of an epidemic of tuberculosis among the cattle in the Preakness Valley, most of which were taken into the State from New York, it is said, in violation of the State laws.

Gifts to Charities.—The New York Society for the Relief of Ruptured and Crippled receives $5,000, and the New York Society for the Relief of the Destitute Blind $10,000 by the will of the late Mrs. H. M. T. Holly of New York.

Dr. Charles J. Kipp of Newark, N. J., by his will gave all his medical books and instruments to the Newark Charitable Eye and Ear Infirmary.

Yale University has received a bequest of $25,000 from the late Dr. Cyprian Brainerd of the class of '50 for the use of the medical department.

Obituary Notes.—Dr. John Lawrence Hughes of Mount Vernon, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1899, a member of the American Medical Association, the New York State and County Medical Societies, and the Mount Vernon Medical Society, and health officer of Mount Vernon, died in the New Rochelle Hospital on September 20, from injuries received in an automobile accident a few hours before, in the thirty-seventh year of his age.

Dr. Warren H. Hunter of Chicago, Ill., a graduate of the Rush Medical College, Chicago, in 1896, chief coroner's physician of Chicago, and a member of the Illinois State and Cook County Medical Societies, died in the West Side Hospital, Chicago, from blood poisoning contracted in the course of his official duties, on September 4, aged 44 years.

Dr. John Thomas Knowles of Springfield, Mo., a graduate of the Memphis Hospital Medical College, Memphis, Tenn., in 1909, and a member of the Missouri State and Greene County Medical Societies, died at his home of typhoid fever on September 1, aged 33 years.

Dr. Harold T. Prentiss of Holyoke, Mass., a graduate of the University of Pennsylvania, Department of Medicine, in 1894, died at his home after a long illness on September 14, aged 43 years.

Correspondence.

THE FIFTEENTH INTERNATIONAL CONGRESS ON HYGIENE AND DEMOGRAPHY.

(Special Report to the Medical Record.)

OPENING SESSION—ADDRESS OF PRESIDENT TAFT—RESPONSES FROM FOREIGN DELEGATES—PUBLIC HEALTH ORGANIZATION AND ADMINISTRATION IN ENGLAND—INSTRUCTION IN CHILD HYGIENE—BREATHING EXERCISES IN SCHOOLS—THE HYGIENE OF THE TEACHER—FAVUS IN THE SCHOOLS OF MEXICO—TRANSMISSION OF DISEASES BY BOOKS—SYPHILIS AND GONORRHEA IN CHILDREN—EFFECTS OF TEMPERATURE AND HUMIDITY ON FATIGUE—FATIGUE FACTORS IN OCCUPATIONS—FATIGUE IN INDUSTRIAL WORKERS—FOOD PRESERVATIVES—SEXUAL DISEASES IN THE ARMY—DUST AND FUME IN INDUSTRY—AERIAL AND CONTACT INFECTION—INFECTED ROOMS AND FOMITES—DISINFECTION OF STOOLS—CUBAN HEALTH ADMINISTRATION—CONTROL OF RABIES—MUNICIPAL VENEREAL CLINIC—FOUNDLINGS—INFANT MORTALITY.

Washington, D. C., September 23 and 24, 1912.

About three thousand delegates, members, and visitors were present at the opening of the Fifteenth International Congress on Hygiene and Demography which took place in Continental Memorial Hall. The President of the Congress, Dr. Henry P. Walcott of the State Board of Health of Massachusetts, made the opening address. He stated that Massachusetts was the first State to frame a sanitary code and that now forty-eight States have codes which are essentially the same, though differing in detail. He showed how these health boards had gradually developed their functions from those that were merely advisory to such as are actually executive. This process was sometimes slow because the executive power was lodged with the people and it was first necessary to educate the people as a whole. He explained that the reason the enforcement of health laws devolved on the several States was because they had existed individually before the Federal Government and had retained all the functions not transferred to the central authorities. In view of the lack of knowledge in regard to sanitation and the ineffectiveness of early quarantine measures it is not at all surprising that when the Federal Government was organized in 1787 no provision was made for the institution of sanitary measures. Likewise the census was taken merely for finding how many people there were, without any idea of the value of statistics in relation to health and disease. Later, when some of these problems were attacked, it was found convenient to assign this work to the Treasury Department and the Marine Hospital Service. All the political parties were now inviting attention to the need of a separate department which should have charge of all matters pertaining to the public health and should be so designated that all the world may know the work carried on under its direction. He spoke of our victories over cholera and yellow fever, the latter giving us more trouble than any other pestilence and coming as far north as Boston. He also described the brutal force of unscientific quarantine in former times. President Taft then arrived and Dr. Walcott introduced him, saying that this was the first time in the history of the Congress that the ruler of the country in which the meeting was held had been present and willing to assume a share of the responsibility.

President Taft referred to the progress made by the medical profession during the past forty years as being far greater than that made by any other profession and prophesied that if the high aims of investigators and benefactors of humanity should continue during the next century they would discover the fountain of youth so earnestly sought by early discoverers. While he did not wish to be understood as saying that the study of sanitation had its beginning with the Spanish-American War, this event, comparatively insignificant in itself, had made evident the need of sanitation in the tropics. Out of this war came responsibilities in Cuba and the Philippines which necessitated the establishment of governmental institutions in the tropics. In the tropics diseases show themselves on a larger scale and exert an influence on large bodies of men to a more marked degree than in temperate zones; hence the problem of making the tropics habitable presented itself. This problem had been solved not only for government employees who had been sent there but for the entire population and it has been shown that it is possible by proper health methods and proper treatment to revitalize the tropical races and secure to them that physical vigor which will enable them to develop the marvelous resources of the countries in which they live. The problem of enforcing health regulations against the will of an ignorant people required a strong government and the raising of sufficient funds by taxation to support an adequate police. With the present tendency to lodge more executive power with the people it remained to be seen how this would work out.

"There is no difficulty in running a government cheaply if you limit its functions to the preservation of peace and the administration of justice; but if you propose to add to these systems of education, good roads, government hygiene, and other improvements, you must look about for sources of revenue which are not always forthcoming and you must educate the people to understand the importance of the hygienic restrictions and of imposing upon themselves the burden of taxation which it is essential for them to carry in order that progress may be made."

In speaking of the success achieved in the prevention of tropical diseases in the Canal Zone, President Taft said that the building of the canal would have been an impossibility but for the solution of problems of hygiene and that it was fitting and proper that the health officer who had made this achievement possible should upon its completion share equally in the honors with the engineer.

With regard to the value of the Congress he said he could not conceive of any organization being more useful, because the comparison and discussion of ideas and theories by men engaged in the same hunt for truth would necessarily give an impetus to hygiene, sanitation, and demography the world over; and again because the Congress was one of those shining instances of world-wide organization in which the interests of humanity occupied the first place, in contrast with the selfishness and conflict of interests typified by our burdensome and ever-increasing preparations for war. Such a Congress having representation from all the world offered to the scientific student who was willing to devote his life to the search for knowledge that would add to the health, comfort, and happiness of his fellow a reward that could not be measured in money, but was to be found in the consciousness of duty well done.

In regard to the creation of a national health department, the President said that we should develop under governmental auspices a department which should support research in hygiene and preventive medicine. Something of this sort might grow out of the present United States Public Health Service, but there was reason to believe that there should be a widening of its scope of duties before it can perform the function that the medical profession of this country has a right to expect from the general government.

Geheimrat Prof. Dr. Max Rubner, Königl. Freidrich Wilhelms Universität, Berlin, Germany, President of the Permanent International Commission of the Congresses of Hygiene and Demography, opened the plenary sessions, giving an address entitled: "A Presentation of the Significance of Hygiene and Demography as Regards the Sanitary Measures Adopted by Nations with Special Reference to International Cooperation, and with a Historical Survey of the Subject." This was followed by reports as follows: For Argentina, Surgeon Dr. Juan G. del Castillo; for Austria, Dr. Arthur Schattenfroh; for Hungary, Prof. Francis Tangl, Court Councillor, Professor at the University of Budapest; for Belgium, M. Velghe, Director General of the Administration of the Service of Health and Hygiene; for Brazil, Dr. Alfredo da Graca Couto, Inspector of the Service of Isolation and Disinfection, Federal Government of Health, Ministry of Justice and Interior; for Chile, Fleet Surgeon, Major Alberto Adriasola; for Denmark, Dr. A. C. J. Bornemann, Chief of the Medical Corps of the Navy Department; for Dominican Republic, M. Francisco J. Peynado, Envoy Extraordinary and Minister Plenipotentiary; for France, M. Emile Kern, Ingénieur Civil, Président de la Société de Médicine Publique et de Génie Sanitaire; for Germany, Dr. Rubner, Geheimer Medizinalrat, Universitätsprofessor, Direktor des Physiologischen Instituts der Universität, Berlin; for Great Britain, Dr. Theodore Thomson, Local Government Board (representing those British Colonies not represented separately); for Canada, Dr. Frederick Montizambert, I.S.O.Edin., F.R.S., D.C.L., Director-General of Public Health; for Greece, Dr. L. L. Caftanzoglu, LL.D., Chargé d'Affaires; for Guatemala, Señor don Joaquin Mendez; for Italy, Prof. L. Pagliani, University of Turin; for Japan, Mr. Seiji Tsukamoto, Councillor of the Department of the Interior; for Norway, Prof. Axel Holst; for Russia, M. Zort, Councillor of the State and Physician of the General Staff of the Chief of Brigade of Ships of the Line of the Baltic Sea Squadron; for Siam, Prof. Paul G. Woolley; there were also reports from the official delegates from Bolivia, Costa Rica, Cuba, Mexico, Netherlands, Spain, Uruguay, and Venezuela.

In the afternoon a reception was given to the visiting members and ladies by President Taft at the White House, after which several of the sections met at their respective meeting places; among these was a joint meeting of the Section on State and Municipal Hygiene and that on the Hygiene of Traffic and Transportation, which was presided over by Dr. Frank F. Wesbrook of Minneapolis, President of the Section on State and Municipal Hygiene. The session was given up to a symposium on Public Health Organization and Administration by British and German health officials. Dr. Theodore Thomson, C. M. G. Chief Assistant Medical Officer, Local Government Board, London, read the first paper, on "Public Health Administration in England." The Local Government Board was established in 1871 as a Central Department and stood in advisory relation to 1822 sanitary districts and 62 administrative counties. The head of this Local Government Board ranks equally with the Secretary of State and other cabinet ministers. The inspection of factories rests with the Department of State. There is a separate commission on lunacy. The Board of Education also has a medical department. The lesson that their system of administration seems to show is the possibility of cooperation and its effectiveness between different health agencies. By their system every sanitary district was prepared to care for contagious diseases and provisions were rapidly being made for the care of those afflicted with tuberculosis; where the district was not able to stand the expense help was given from the insurance fund and the exchequer. They also maintained schools for defectives. The careful keeping of statistics was one of the duties of each local officer and he was required to present his report quarterly and annually to the Local Government Board. The housing and Town-planning Act, passed in 1909, had increased the authority of both the local and central health boards in suggesting repairs and regulating new buildings. The Local Government Board prepared model by-laws for the regulation of lodging houses, street planning, building, removal of refuse, etc., which could be used as guides by local authorities.

Dr. Weber of the Imperial Board of Health, Berlin, then spoke of the Public Health Administration for the Empire and Dr. Schneider, of the Royal Prussian Ministry of the Interior, described the health administration in Prussia.

The Section on Hygiene of Infancy and Childhood, which was presided over by Dr. Abraham Jacobi, had a very large attendance. Dr. Mary Sutton Macy of New York read the first paper, on "Instruction in Child Hygiene," in which she especially called attention to the deficiency of the literature on personal hygiene of childhood. She thought sources for instruction in child hygiene should be made available for parents, teachers, and the general public. She showed that there was great need for such instruction and told of the activities in such instruction that have been carried on in New York during the last few years. Dr. Ira S. Wile of New York submitted a plan for teaching school hygiene which can be used in the elementary schools. He believes this is the place to teach the basis of social hygiene, as 94.5 per cent. of school children fail to get above the elementary school. His plan consists of graded syllabic lessons based on a correlation of existent courses in nature study, physiology, hygiene, domestic science, civics, etc., without the introduction of new studies and without any additional cost to the educational authorities. The average child will grasp and appreciate the facts essential to the correct mode of living whereas it lacks the interest necessary to stimulate attention in the present mode of teaching physiology. To understand the dominating rules of life as they apply to the individual and to perceive the relation of these individual rules to the life of the family is far more reasonable to the child mind. Once grasping the relation of personal hygiene to the health of the family a stepping stone is laid to an intelligent conception of the relation of individual hygiene to the health of the community.

Dr. S. Adolphus Knopf of New York made a

plea for breathing exercises in schools and gave a detailed description of a series of exercises which could not help but be of value in the development of the chest of the child or adult. Dr. Knopf also made a plea for more out-door instruction. Whenever the weather permits, singing and recitation should be done out-doors and natural sciences should be taught in the open air. The typical out-door school for summer and winter, conducted under well-known precautions, should be the rule rather than the exception.

"The Hygiene of the Teacher" was the subject presented by Dr. Grace Kimball of Poughkeepsie, N. Y. She called attention to the tendency to consider only the pupil in school construction and appointments. She pointed out the shortsightedness of a policy which did not furnish a proper environment for the teacher and which showed no consideration as to the amount of work required. Overwork and under-pay lessens efficiency and the pupils suffer as well as the teachers. The fundamental responsibility for hygiene and increased efficiency of the teacher rests with society. She should receive such compensation as will relieve her of domestic duties out of school hours.

In discussing this paper a member of the Health Board of Kansas City called attention to a very general omission in our health work, and that is the neglect to require all applicants who wish to teach to submit to a physical examination. It is a menace to the pupils to permit a person to teach who is tuberculous, neurotic, or hysterical. One might even go a step further and require girls to pass a physical examination before being admitted to schools that prepare teachers.

Dr. Manuel Uribe y Troncoso of Mexico City, Mexico, related the history of their struggle with favus in the schools of Mexico. During the school year 1910-1911, 2,784 pupils were separated from the public schools because of favus. About 8.2 per cent. of all pupils were affected by the parasite. The disease was widely disseminated not only in the public schools but in the private schools also. They made use of the *x*-ray treatment, which reduced the duration of treatment to two or three months. There were two special schools in the City of Mexico for pupils affected with favus, and the children thus lost no time from school and were at the same time kept under observation and treatment.

Dr. William R. Reinick discussed the "Transmission of Disease by Books." He showed that books presented favorable conditions for the preservation of bacteria and said that it was impossible to disinfect them, as hot air and steam will not penetrate, but will ruin books. Dust taken from books in Florida which had been untouched for thirty or forty years showed many species of bacilli still living.

"The Occurrence of Syphilis and Gonorrhea in Children by Direct Infection" was the subject of a paper read by Dr. Abraham L. Wolbarst of New York, in which he stated that these diseases occurred much more frequently in children than was supposed. The danger of direct infection of the eyes at birth was, of course, avoidable and unnecessary. He blamed unhygienic conditions and lack of privacy in the homes of the poor as leading to sexual precocity which unscrupulous and ignorant adults were not slow to take advantage of. Uncleanly catheters used in hospitals and uncleanly bathing in institutions were also responsible for infections. Girls were much more frequently infected than boys.

In the Section on Hygiene and Occupation under the presidency of Dr. George M. Kober, professor of hygiene, Georgetown University, Washington, D. C., there was an interesting paper on "The Effects of Temperature and Humidity on Fatigue" by Prof. Frederic S. Lee of New York City. He said that with human beings the relation between temperature, humidity and fatigue was shown most clearly in life in the tropics and in those industrial occupations in which the individual was obliged to labor in a hot atmosphere containing much moisture. Not only are sensations of fatigue there common, but the power of performing work is distinctly lessened and actual fatigue comes on earlier. The evaporation of sweat and the accompanying elimination of bodily heat is lessened by the high external humidity, and the body temperature therefore rises above the normal, and a febrile condition results. He claims that this febrile condition affords the proper chemical conditions for a pronounced susceptibility to fatigue. In the body laboring in an atmosphere of an elevated temperature and charged with much moisture, conditions were found that were needed for the early oncoming of fatigue; there were a store of toxic fatigue substances and tissues possessing an unusually great susceptibility to the action of such substances.

Prof. Shepherd I. Franz of Washington, D. C., considered "Fatigue Factors in Certain Types of Occupations." At present there has been investigated only one part of the general problem, viz.: the fatigue effects that result from continued and rapid work, which was more or less complicated in the nature of the movements required. Special reference was, therefore, given to the matter of speeding up, or the carrying on of operations at greater speed than that which the operator would normally assume.

A paper on "The Study of Fatigue and Its Application to Industrial Workers" was presented by Miss Josephine Goldmark, of the National Consumers' League, New York City. The object of this paper was to point out some hitherto unrecognized or neglected aspects of scientific study which might assist in combating that danger of occupation which was more widespread than all others because it affected the larger number of wage earners. The most hopeful methods of combating over-fatigue and exhaustion in industry were two: legislation prohibiting excessive hours of labor and the education of employers. Neither method was sufficient alone. They needed a new study of undue fatigue in industry. The workday was too long when it went beyond physiological limits, when no adequate margin of rest was allowed for tissue repair. They needed to know what was an adequate margin of rest. They needed, above all, men of the highest professional standing to plan such investigation along broad lines, so as to discount what was transient and temporary and to obtain the underlying facts, for the conservation of health and efficiency.

Dr. Clarence John Blake, professor of otology, Harvard Medical School, Boston, believes that the deleterious effects of unnecessary noise are evinced not only in the changes occurring in the organ of hearing as the result of continued exposure to loud noise, but also in the fatigue effect showing itself generally and evidenced by various forms of disturbance of function of the nervous system. He believes that a great part of the noise incident to the mechanical operation of modern life is avoidable. The suppression of unnecessary noise is, therefore, advisable for economic reasons, both in

the safeguarding of the human machine and in the saving of wasted mechanical energy, of which the noise is an evidence—a saving of waste in two directions.

In the Section on Dietetic Hygiene and Hygienic Physiology, under the presidency of Dr. Russell H. Chittenden, professor of physiological chemistry and director of the Sheffield Scientific School of Yale University, New Haven, Conn., a paper on "The Physiological Significance of Some Substances Used in the Preservation of Foods" was read by Dr. John H. Long, professor of chemistry, Northwestern University Medical School, Chicago. This paper deals with the action on the human organism of a number of substances employed as food preservatives, or otherwise, in the preparation of food. It was shown that a considerable number of substances are added to food largely because of their preservative properties, rather than because of flavors they may impart. Some of the so-called "natural" preservatives come under this head. Modern conditions of living and modern scientific advances have called for the introduction of more efficient bodies, the so-called "chemical" or "artificial" preservatives. Many of these bodies have been condemned, and perhaps properly, but frequently the condemnation is solely on the ground of their origin. This basis of condemnation has no justification in fact, as all preservatives are as truly chemical as are those of recent introduction made by industrial processes. The active principles in cloves, cinnamon, allspice, etc., are true chemical compounds, and in their action on the body and final disposition are much like benzoic acid, now made largely by laboratory processes. A number of important investigations on the physiological action of sodium benzoate have been carried out in the last few years. The effects of large and small amounts of benzoic acid are known, and it has been clearly shown that the use of the small quantities employed in the ordinary protection of the condimental foods is quite unobjectionable. Such small amounts are normally disposed of in the human body without ill effects. The use of copper salts in coloring vegetables he discussed. There is an enormous literature on the subject, especially from France and Germany, where copper has long been used in the canning industries. Several commissions have pronounced in favor of permitting the use of copper salts, although others have opposed it. But all authorities have come to agree that the toxicity of these salts is much less than was at one time assumed. This toxicity depends somewhat on the combinations in which the salts are ingested. The effects of copper as used in young peas or string beans are far less marked than are those of inorganic salts. It is, therefore, not quite justifiable to draw conclusions as to the behavior of copper from experiments with copper sulphate alone. If only very young and fresh vegetables, with plenty of chlorophyll, were treated with copper, and if the amount were strictly limited, there might be but little fault found. But with older vegetables the combination is far less stable and the effects approach those of the inorganic salts. The amounts of copper taken up by the liver and other organs from inorganic salts may be considerable, and such absorption cannot be held free from danger. The use of these salts serves no real good purpose and should be condemned.

In the Section on Military, Naval, and Tropical (Colonial) Hygiene, under the presidency of Medical Director Henry G. Beyer, U. S. Navy, Washington, D. C., in a symposium on "Fighting the Sexual Diseases in the Army," the opening paper was by Oberstabsarzt Professor Dr. von Vagedes of Danzig, Germany, who gave a brief survey of the spread of sexual diseases and the measures which had proven practical and successful, especially in the German army. Statistical facts were given in stereopticon views.

Colonel L. Mervin Maus of the U. S. Medical Corps read a paper on "Venereal Prophylaxis in the Army," giving his reasons for the increase of venereal diseases since 1900. One was the poor character of the recruits. Again there was the undesirable location of the recruiting stations in large cities. A number of men were accepted suffering from chronic gonorrhea. Venereal diseases were a great factor in the non-efficiency of troops and he spoke of their racial and geographical distribution. Semi-prostitutes were large factors in disseminating venereal diseases. Previous to the Spanish-American War venereal diseases were regarded with official indifference. Inspections or forced treatment was not practised before that period. There was a special inspection of troops before embarkation for Cuba, Porto Rico, and the Philippines and a general examination of volunteer regiments before mustering out of the service. There were given health lectures and moral suasion as measures for the prevention of venereal diseases. There was the regulation bi-weekly inspection by a medical officer, as well as the weekly inspection by an instructed non-commissioned officer in the presence of the company commander.

Medical Inspector George A. Lung of the U. S. Navy read a paper on "Venereal Prophylaxis" and called attention to the conditions suggesting need of unusual methods for lessening incidence of venereal diseases in the navy. Major Deane C. Howard of the U. S. Army, believed that venereal diseases in armies not entirely eradicated were yet preventable in great part. Effective measures applicable in the U. S. Army are directed chiefly to the individual soldier. The sources of infection (prostitutes) are beyond military control, and there should be effective regulation and sanitary supervision of prostitution by the civil authorities; this was unlikely because of public sentiment. The valuable measures of prophylaxis applicable in the U. S. Army were as follows: 1. Educational and moral measures, through lectures by medical officers, moral talks by chaplains, informal advice, venereal pamphlets, are desirable but of limited value. 2. Recreative features, athletics, soldiers' clubs, gymnasia, reading rooms and other wholesome amusements in garrison. 3. Physical inspection (bi-monthly) of all soldiers for concealed cases of disease essential. Every known case of disease should be made of record and treated in hospital. When discharged, the case should be kept in semi-quarantine, and under prolonged observation and treatment to prevent re-exposure or relapse. 4. Personal prophylaxis is of greater value than all other preventive measures combined. Fully 80 per cent. of venereal infections are preventable if proper treatment is given within 10 hours following coitus. The treatment should be given by or under the supervision of a trained hospital attendant. The treatment must be made mandatory by military order, which must be strictly enforced by summary punishment for non-compliance. Mandatory individual prophylactic treatment following exposure was initiated at Jefferson Bar-

racks, Missouri, in August, 1911. The treatment consists in (1) thorough cleansing of genitals with 1-5000 mercuric chloride solution; (2) injection of 4 c.c. of 20 per cent. argyrol solution into the anterior urethra; (3) the application of two to four grams 30 per cent. calomel ointment to the entire penis. Accurate record is kept of each treatment in a permanent register.

On the evening of September 23 Sir Thomas Oliver of the College of Medicine, University of Durham, England, addressed the General Session on the subject of "Dust and Fume, Foes of Industrial Life." He said that it was never meant that labor should be anything else than a source of health and wealth to man. Trades should be free from danger. In modern industrial life we are struck with two things: 1. The effect of the occupation upon those who follow it; 2. the influence of industries upon localities. With the rise of industrial prosperity in Germany the death rate from acute pulmonary diseases has increased and the increased mortality rates bear a distinct relation to the size of the town, the density of the population, and the social well-being of the people. Smoke-laden atmosphere predisposes to acute lung diseases and also hastens the course of tuberculosis. The dust of our roads and streets is responsible for the early decay of vegetation and is also harmful to animal life. Dust in coal mining is one of the greatest problems of modern industrial life. This dust is not only prejudicial to health but is a source of explosions. While firedamp was formerly regarded as the cause of explosions there is a growing conviction that dust plays the more important part. Sir Thomas Oliver related the methods that have been used in the endeavor to prevent explosions by sprinkling with stone dust and the use of colloidal substances and said that he believed the laboratory would yet solve the problem. Hitherto men overcome in the mines by the gases evolved from explosives have been supposed to be suffering from the effects of nitrous fumes. The speaker hardly takes that view. In his opinion the symptoms are the result of carbon monoxide poisoning. Occasionally, chronic carbon monoxide poisoning is observed in blast furnace men. The symptoms resemble those met with in general paralysis. Sir Thomas Oliver, after congratulating the United States Government and the American Association for Labor Legislation upon the former having passed into law a bill which deals with the use of white phosphorus in the manufacture of lucifer matches, described the evil effects of the metalloid as shown in the general malaise or constitutional state of ill-health occasionally met with in lucifer matchmakers and known as "phosphorisme." In speaking of the relation of dust to tuberculosis he said: "There is always the possibility of dust, especially in workshops, becoming contaminated by the tubercle bacillus. Apart from such infection there is the harmful influence exercised by dust as dust upon the lungs, whereby they cease to be of a loose, spongy texture and are converted into a hard unyielding mass of almost solid tissue. All this structural change can be brought about by the reaction to the physical effects of dust. Coal miners' phthisis or pulmonary anthracosis, gold miners' phthisis, and the lung affections of the Sicilian miners are in their early stages non-tuberculous affections, but, as the disease progresses and vital resistance diminishes, the lungs subsequently become infected by the tubercle bacillus."

In the Section on the Control of Infectious Diseases, which met for the first time on Tuesday morning under the presidency of Dr. Herman M. Beggs of New York, Dr. Charles V. Chapin of Providence, R. I., read a paper on "Relative Importance of Aerial and Contact Infection in the Dissemination of Contagious Diseases," which was very enthusiastically received. He made the point that infection by air is of minor importance, if not an entirely negligible factor. The existence of carriers and mixed cases affords such ample opportunity for infection by contact that the theory of aerial infection is no longer required by a *priori* reasoning. In proof of this statement he directed attention to experimental and epidemiological evidence. The observations around hospitals and dwellings show that scarlet fever and diphtheria are not carried by the outer air. Bacteriologists tell us that tuberculosis probably is not. Careful analysis shows that there is no validity in the claim of certain English observers that smallpox may be carried a mile or more from a hospital.

With regard to air infection indoors, he said it was theoretically possible that diseases might be transferred through the air of houses and hospital wards, though the virus might be too diluted in the outer air to do any harm. "Malaria and yellow fever, in the absence of mosquitos, are never transferred from bed to bed. Hospital infection rarely occurs in cholera and typhoid fever, and when it does, is traced to contact infection. The bubonic type of plague, Mediterranean fever, cerebrospinal meningitis and poliomyelitis do not spread in hospital wards. Ample epidemiological evidence, as well as experiments by Horrocks, and the work of the English Plague Commission, have demonstrated that Mediterranean fever and bubonic plague are not air-borne. Typhus fever is transferred by biting insects, and the experience of Edinburgh, Liverpool, and Mexico shows that infection by air does not occur in hospitals. Work done in France, England, and the United States has shown that diphtheria and uncomplicated scarlet fever are not air-borne under such conditions. Opinions are divided as to measles. The trend of English opinion is that smallpox and chicken-pox are occasionally air-borne and perhaps also rubella, and whooping-cough. This is probably not the usual mode of infection."

Another prominent feature of this session was a symposium on the Control of Disinfection and the Influence of Infected Rooms and Fomites in the Dissemination of Various Infectious Diseases, in which Dr. Borne, Médecin des Épidémies du Département de la Seine and Dr. Ott, Inspecteur Départmental du Bureau d'Hygiene de la Seine-Inferieure, presented papers and Dr. Alvah Doty of New York sent a communication which was read by the secretary, in which it was stated that money and rags were not so often responsible for the dissemination of contagious diseases as was generally supposed. Contagion might rarely be conveyed by this means, but as a rule, persons and not things were responsible. Transference of disease is usually effected by means of discharges, and if these are properly destroyed and general cleanliness observed we have done all that is required from the standpoint of medical sanitation. He showed the uselessness of many of the methods of disinfection. It has been found in experimenting with the feces of typhoid patients that when these were soaked in dilute carbolic for twenty hours the disinfection

had not penetrated one-eighth of an inch. He concluded that our best disinfectant is heat.

Dr. M. Prausnitz, Hygienisches Institut der Universität Graz, Austria, gave a demonstration of a simple and certain method devised by M. Kaiser for disinfecting stools at the bedside. This is done by estimating approximately the amount of water necessary to cover the stools without actually pouring it on. One-quarter of this volume of quicklime is then added to the stools and then the amount of water needed to cover the stool is added. He claimed that the disinfection took place because of the heat generated, but some of those present thought that quicklime being an exceedingly powerful agent might have something to do with the result.

Dr Liberati, one of the officials of the Cuban Health Department, described the work of that body. He attributed their great success in combating tropical diseases to the organization, harmony, and coordination that existed in the health department. In the struggle with yellow fever they had expended a vast amount of money and labor, but the knowledge gained had been very useful in combating other diseases. Much of their success was due to the thorough system of inspection and the isolation of suspects. He described the method used in fighting the plague in June, 1912. When the commissioner sent to Porto Rico to investigate called attention to the danger from rats and fleas and it was noticed that an unusually large number of rats died about the warehouses, a campaign of extermination was begun and he believed that their energetic action in this respect prevented an epidemic. After comparing the danger from the cutaneous form of plague and the pneumonic form, he said that accurate clinical diagnosis was not possible in many cases and it was important that a bacteriological diagnosis should be made as soon as possible. On this account the microscopical examination of the smear was the method to be preferred, but where this was not satisfactory they had to resort to the inoculation of guinea pigs. In the latter method it required from five to seven days to make the diagnosis. He spoke of the difficulties met with in dealing with rats. It seemed important to subject all rats killed to bacteriological examination, but if this examination was not made very shortly after the death of the rat the result was negative. During the campaign against the rats they had endeavored to have all rats delivered for examinations and deliveries were made three times a day.

In the afternoon Prof. Henry Albert of the University of Iowa read a paper in this section on the "Control of Rabies," which called attention to the need of immediate treatment for this disease, the need of more rigid regulations and united action on the part of states and provinces. "The control of rabies should mean the extirpation of the disease." He made a plea for a united effort on the part of the governments of the United States, Canada, Mexico, and Central America for the complete eradication of the disease from the American Continent and of similar action in other localities.

Another paper of interest was that of Dr. Julius Rosenstein of San Francisco, who described the municipal clinic for venereal diseases in his city and its administration, the method of medical examinations of prostitutes, and the methods of dealing with them. The results from the statistics of 20,000 complete examinations with data on 2,500 individuals showed that good results were secured in consequence of control of morbidity. There were certain features connected with the work in San Francisco which made it more effective than that done in European cities.

Dr. Homer Folks of New York addressed the Section of Child Hygiene on "Foundlings." These he divided into two classes: real foundlings and so-called foundlings, or those taken to institutions by parents who for various reasons desired to be relieved of the responsibility of caring for their offspring. Statistics seemed to indicate that for one real foundling there are 20 so called. There were 2,500 in New York and of these 2,000 had been received in one institution. The real foundlings came into the world mostly healthy and were put under care while still in good condition and their mortality ranked favorably with the mortality of other infants in the same locality, while statistics seemed to show that one-half of all so-called foundlings die. That we should have so many so-called foundlings was wholly unnecessary, indefensible, and shockingly wicked. We should not receive these so-called foundlings into our care at all. Where there were the largest number of so-called foundlings there the largest number of real foundlings were also found and there were no evidences in a study of statistics to indicate that a refusal to accept so-called foundlings had any effect on the number of cases of infanticide or abortion. Abandonment of a child in a railroad station or public place is not essentially different from abandoning it at the doors of an institution. The better method would be to accept no infant unless authorities chosen for the purpose show that the mother is unfit to care for her child.

Dr. Samuel McC. Hamill of Philadelphia described the development of an exhibit which showed the causes of high infant death rate and the means of reducing it. The exhibit first showed the effect of prenatal influences and taught the proper care of the expectant mother and then the various details in the care of the new-born babe. The exhibit was practical and compact and it was possible to get a very comprehensive idea of it in a couple of hours.

In the discussion of these papers special emphasis was laid on the fact that mortality statistics in institutions for infants were not to be relied upon, that a certain number of abandoned infants came into institutions in such an apparently hopeless condition that nothing was done for them, that frequently there were not enough nurses to properly care for the large number of babies. Dr. Jacobi held that the fact that the infants in institutions were mostly artificially fed ran the mortality rates up, as it was well known that only 7 per cent. of breast-fed infants died, while from 19 to 20 per cent. on good artificial feeding died. The question of providing help which would enable mothers to care for their infants was discussed. The desirability of such help in many instances is unquestioned, but the advisability of enacting legislation for this purpose is open to debate. The importance of home life and home care for the child should, however, be emphasized.

Dr. Totten of Syracuse gave statistics in regard to 165 new-born babies in Syracuse, N. Y., during July and August of this year under the "follow up" system. Ninety-seven per cent. of these babies were breast-fed and there had been no mortality.

(To be continued.)

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ASSOCIATION FOR ADVANCEMENT OF SCIENCE, PRESIDENT'S ADDRESS ON ORIGIN OF LIFE.

LONDON, Sept. 6, 1912.

THE British Association for the Advancement of Science, or as we colloquially call it "for short" simply the British Association, opened its annual meeting on Wednesday at Dundee. The President this year is Professor Schäfer and he delivered his address the same evening in the Kinnaird Hall, the total capacity of which is only 1,800, and many members were disappointed at finding it crowded—for more than 2,000 had arrived in the gray stone city. The Lord Provost invited the foreign members, who were more than usually numerous, to meet some of his distinguished fellow citizens in the afternoon, and this innovation in the proceedings was generally approved. He wore his robe of office as did the other officials and the door of the council chamber was guarded by halberdiers as in the olden time. An attempt is being made this year to induce members to appear in their academic gowns, and as the association appeals to the popular imagination as well as to the purely scientific, this may not be unnatural.

Sir Wm. Ramsay, the outgoing President, was unable to be present, as he is president of the International Congress of Applied Chemistry now meeting in New York, and it was his duty to induct his successor. He sent an appropriate message and Sir Archibald Geikie discharged his duty and formally introduced the new President, who then gave his presidential address on the "Origin of Life." The vote of thanks proposed by the Lord Provost having been duly honored and the President having returned thanks the Lord Provost once more rose and expressed the pleasure he had in handing to the President a cheque for £10,000 on behalf of Mr. J. K. Cairds, LL.D., of St. Andrew's, a Dundee manufacturer and a vice-president of the Association, whose munificence to the poor and to medical institutions for their benefit is said to have exceeded in the last 15 years £100,000. In acknowledging the gift the President said it was unique in the history of the Association and would be strictly devoted to advancing science.

To return—the subject of the address is a well-worn one and no new light was shed upon it, though some modern points were re-stated, felicitously enough and many pens are set to work upon it.

Prof. Schäfer attempted no definition of life, a word interesting him as one of those abstract terms which had no direct antithesis. But he declared the problems of life were only problems of matter, apart from which life could not be conceived of in a scientific sense. To enforce this view he referred to spontaneous movements in physical and chemical reactions observed in changes in the surface tension of fluids (oil drops, mercury globules). He held movements ameboid and other as developed by evolution through agencies resembling these. To those who object that such resemblances are superficial and other characteristics are joined with movement (assimilation, dissimilation, etc.), he said such processes also occurred where no one would associate them with life. Division of a cell-nucleus by karyokinesis preliminary to multiplication by division could be imitated with inorganic salt solutions suspending carbon particles. Vitalism as a working hypothesis had been undermined and most of the structure toppled over. "Vital force" was an expression of ignorance. To substitute "neo-vitalism" and "biotic energy" was no advance. "New presbyter, old presbyter writ large." Chemical composition of living matter was not so complex as long supposed. The nucleus of a cell, the quintessence of its life was not very complex and we might therefore hope some day to see its material made synthetically. A few elements combine in a colloidal compound representing the chemical basis of life. When the chemist can build up his colloid he had no doubt it would exhibit phenomena we associate with life. Perhaps the production of living material was not so remote as commonly supposed. Prof. Schäfer spoke of his friend Dr. Charlton Bastian as the only eminent scientist who held to the old creed and he doubted if many were convinced by his numerous experiments. Setting aside as devoid of scientific foundation the idea of immediate supernatural intervention, Prof. Schäfer argued that we must believe living matter owed its origin to causes similar in character to those instrumental in producing all other matter in the universe—*i.e.* evolution. Many biologists, he said, shelved this conclusion by calling in some former condition of the earth when opportunity was favorable to the passing of inanimate into animate material—such opportunities never recurring. But if this happened once it might again and we could not be sure it was not happening now. Prof. Schäfer spoke of parental qualities being transmitted by elements and heredity as possible of solution by chemistry. But cells might cease to be useful and organs, too. Then Nature wanted to get rid of them. He instanced the appendix and Nature's method being too slow surgery was necessary. Here Prof. Schäfer will find plenty of contradiction to his declaration of the uselessness of the appendix.

The President pointed out that plants react to external impressions, but these are only conveyed from cell to cell and having no nervous system plants can never acquire the least glimmer of intelligence, but animals from a slight modification of certain cells proceeded by evolution to a nervous system, culminating by this same evolution in the human intellect. But if the slight change in a few cells did this for animals, and Prof. Schäfer would not be surprised to see them follow on to intelligence, this might even occur in plants, or what becomes of his argument that what happened once may happen again and may even be happening now?

Passing to the end of life Prof. Schäfer said the cells must grow old and eventually cease to function, and when this happens to those essential to life death must result. Here then his vaunted evolution fails—ends seemingly in that death which he has just said "must always remain the universal law." So this word evolution signifies only a process or a series of changes but has no such innate originating power as some biologists have attributed to it; for it only continues for a time, growing old and dying. And that is the explanation of life and all things which these biologists propose as more reasonable than the doctrine of a creative intelligence!

The sectional proceedings began yesterday, most of their presidents giving addresses.

Massage in Wasting Diseases of Children.—J. M. MacPhail states that massage has received a great deal of attention in nervous and in surgical conditions, and that in wasting diseases of children it may effect an improvement when the nursing and natural exercise have been defective.—*British Journal of Children's Diseases.*

Progress of Medical Science.

Boston Medical and Surgical Journal.

September 12, 1912.

1. The Operative Treatment of Gastroenteroptosis. J.Ransohoff.
2. Medical Aspect of Intestinal Adhesion and Ptosis. J. M. Jackson.
3. Dangers Incurred as a Result of the Non-Recognition of Acute Aural Infections with Statistical Data. F. E. Kittredge.
4. Inversion of the Uterus. H. F. Day.

1. **Operative Treatment of Gastroenteroptosis.**—J. M. Ransohoff states that every case of visceral sagging should be studied individually, and should not be treated in a routine way, whether conservatively or by operation. If after the removal of the normal or nearly normal appendix the patient continues to suffer, he should not be lightly classed among the hopeless neurotics. It is probable that the surgeon has overlooked some visceral displacements or adhesions which are the cause of the suffering. A small incision in abdominal work of the kind under consideration has signal disadvantages. The conclusion of the internists based on laboratory findings as, for example, after ingestion of a test meal, cannot be made the basis of the functional capacity of the stomach under everyday conditions. In many seemingly hopeless cases of gastroenteroptosis with marked neurasthenic symptoms operation promises relief. If this is the result of suggestion it is none the less valuable if the relief is permanent. While, of course, internal treatment, abdominal supports, and postural treatment should be tried, operative interference should not be unnecessarily delayed lest the habitus nervosus become too deep-rooted to be eradicated. No gastroptotic patient should be operated on unless some actual functional disturbance can be demonstrated. To relieve this must be the aim of the operation. Given a visceroptosis in which one can demonstrate distinct functional incompetence or deviations the existence of nervous phenomena does not militate against operation but may be the chief reason for performing it.

2. **Medical Aspect of Intestinal Adhesion and Ptoses.**—J. M. Jackson lays particular stress upon colitis as an important symptom of adhesions. He does not believe that there is any such thing as hysterical colitis. In typical cases of stasis one always finds a definite group of symptoms. Following a period of constipation with more or less attendant indigestion, anorexia, hyperacidity, bloating and feeling of pressure, all of which grow steadily more severe, the patient begins to have abdominal pain which may be described as dull and dragging or colicky, or merely a constant sense of discomfort, relieved only by lying down. It is usually worse when standing or walking or riding in a train or automobile. The colicky attacks may come on without apparent reason, and may or may not be accompanied by nausea and occasionally by vomiting, even of the most marked propulsive type. Distention is usually present, and may come on with great suddenness and severity. These attacks are relieved by morphine and belladonna, high enemata and cathartics, and are followed immediately by a copious discharge of mucus—even as much as a quart at one dejection—and in smaller quantities usually for several days. Following this "clearing out" the patient is apparently well for a time varying from days to weeks, when the cycle begins over again. The ptoses of the cecum, transverse colon and sigmoid are all characterized by similar symptoms due to their weight and abnormal positions and to partial obstruction. In prolapse of the cecum a kink is sometimes formed in the ileum near the ileocecal valve. As this dams back the contents of the ileum fermentation takes place there and the entire small intestine may become distended with gas, producing discomfort, distress, or severe pain. In the treatment of this condition licorice powder is of the greatest service, especially in conjunction with a diet largely of vegetables, as is also the use of agar-agar. When colitis is present small doses of salol and castor oil are of the greatest service, and when toxemia exists great help is afforded by the exhibition of calomel once a week. High irrigations; oil, either by mouth or by enema; a coarse diet (vegetables, fruit, bran biscuits, coarse cereals); exercises, and abdominal massage may also be employed to advantage. In the acute attacks, however, simulating intestinal obstruction nothing gives relief except the administration of efficient doses of morphine and belladonna.

3. **Acute Aural Infections.**—F. E. Kittredge notes that the one safe course to pursue to avoid deeply seated aural infections, together with their intracranial complications, is the practice of preventive surgery. A free incision of the drum membrane made as quickly as possible following a diagnosis of probable presence of fluid in the middle ear cavity will in the great majority of cases prevent further difficulty. Spontaneous rupture of the tympanic membrane does not necessarily mean free drainage, and by no means contraindicates further interference by the physician. If pain continues, even to a slight degree, or if there is any rise of temperature, it would mean impeded drainage, and there should be no hesitation in freely incising the drum. This procedure is not alone for the purpose of preventing a more dangerous condition, but it hastens convalescence and may prevent a chronic running ear with its attendant discomforts. A clean linear incision heals promptly with no interference of hearing, while a spontaneous rupture through a swollen and ruptured membrane heals by cicatrization if at all and interferes with the normal function of the ear. Dangerously infected mastoids may be present without presenting the usual symptoms as formerly taught. Swelling posterior to the ear is present only late in the course of the disease; marked tenderness usually subsides with acute inflammatory symptoms, and the temperature chart is similar to that of appendicitis, not always a safe guide. The absence of free pus in the mastoid cells does not necessarily mean a case operated upon unwisely, for there may be present in the mastoid antrum and scattered throughout the cellular structure highly infective granulations. This condition is far more dangerous to life in an individual in whom the bone is dense and sclerosed with but very few small cells, than would be the case were a large quantity of free pus present in large pneumatic cells, the outer wall of the mastoid structure being thin. In the latter case the pus might easily rupture through the bony wall externally. In the former condition infection could more readily find its exit internally.

4. **Inversion of the Uterus.**—H. F. Day concludes that inversion of uterus is rare and will be rarer with the decrease of untrained accoucheurs. Acute inversion should be reinverted as soon as possible. Chronic inversion demands operation as soon as the patient's condition warrants it. Thomas' operation is advised if the patient is seen within ten days of occurrence and is not exsanguinated. Spinelli's operation is recommended for later cases of this disease.

2. **Polyneuritis with Radicular and Spinal Cord Involvement.**—W. M. Leszynsky reports an unusual case

of this condition with complete recovery. There were a slowly progressive development of atrophy and paralysis beginning in the ulnar distribution of the left hand until clawhand resulted; some atrophy in both shoulder girdles; a lesser involvement of the ulnar group in the right hand; vasomotor paresis in both hands; absence of subjective sensory symptoms, and no pupillary disturbance. Several months after the onset the lower extremities became implicated, the paralysis being limited to the peroneal group on both sides. There became evident an area of sensory disturbance over the trunk on the left side affecting all forms of sensibility, and an area of incomplete thermoanesthesia over the inner aspect of the left arm. At the end of a year there was a rapid exacerbation of the symptoms in the lower extremities, at which time there was complete bilateral foot drop, hypotonia, ataxia, absence of all reflexes, and slow urination. This continued for a few months, when rapid improvement began and gradually terminated in complete recovery. It is noted that the left side was principally affected, the sensory symptoms being confined to that side. The duration of the disease was one year and eight months.

3. **Early Pharyngeal Symptoms of Poliomyelitis.**—M. Neustaedter calls attention to the nasopharyngeal symptoms which he believes are invariably present in this disease. Frequently one is told that the patient begins to sneeze, or makes attempts to sneeze and the mother or nurse suggests that the patient is developing measles. Upon inspection, however, there is not a red, sore, and hyperemic throat, but rather an anemic, glistening, edematous condition of the pharyngeal mucosa, with a serous frothy transudate, quite analogous to the edematous swelling of the cord. This condition the author has found to persist in the majority of the cases, even several weeks after the onset of the paralysis. This sign, in his opinion, is pathognomonic of the disease.

4. **The Crotalin Treatment of Epilepsy.**—R. H. Spangler believes that the "venom treatment" is indicated in many of the essential cases of epilepsy. Not only are the virulence and number of the epileptic fits favorably influenced by the crotalin treatment, but the excitability of the nervous system is modified and the general health, mental faculties, and metabolism of the patients are considerably improved. The quality of the blood, and possibly its chemical composition seem to be affected by the injection of the venom. As to the exact effect it has on the coagulability of the blood, further observation is necessary. There is said to be no danger in the use of crotalin as long as the necessary aseptic precautions are taken in its administration, and the treatment is carried out with careful observation of its effect on the patient.

5. **Abdominal Drainage.**—J. W. Kennedy ventures the statement that he is entirely and enthusiastically opposed to the modern methods of treating septic conditions of the abdominal viscera. First, he attacks the Fowler position. He believes he has demonstrated that there is very little absorption of toxins in the already inflamed peritoneum and that the difference of absorption between the upper and lower abdomen must be very small if any. The worst cases, with extensive peritonitis and distention, are put in the Trendelenburg position, so as to give the nerve centers more blood and thus to stimulate the shocked and badly infected patient. The author regards adhesions and inflammatory membranes as a wolf in sheep's clothing, as they quickly become complications which are of more pathological import than the existing peritonitis. These inflammatory walls have little physiological integrity and quickly cause a bowel obstruction or the formation of a distal abscess. The gloved hand is also held responsible for much of the incomplete work of the present hour. The author believes that the greatest calamity which has happened to the surgery of intra-abdominal pus and of those extensively infected areas found in diffuse and general peritonitis has been the abandonment of gauze as a drain and the substitution of tubal drainage. The frailty of the modern toilet has made it necessary to abandon the gauze cofferdam for tubal drainage, as it is impossible to insert a cofferdam until one has removed the pathological lesion and broken all adhesions.

9. **Rheumatism and Oral Sepsis.**—A. M. Nodine reaches the following conclusions: (1) Rheumatic fever is an acute or attenuated general infection accompanied by toxemia, autointoxication, chorea, high blood pressure, anemia, carditis, and arthritis. (2) The microorganism, whose toxin is most concerned in the production of the symptoms of rheumatism, is the *Diplococcus rheumaticus* of the streptococcus family. (3) The portal of entry for the infection is the oral cavity. (4) Oral sepsis plays a direct part in the production of rheumatic fever by supplying the necessary conditions for the absorption from the mouth of the pathogenic agents. (5) The correction of the conditions contributing to oral sepsis exert a positive and favorable influence in preventing and curing rheumatic fever.

5. **Candy Medication.**—B. Fantus has sought to devise a perfect candy form for as many different important medicaments as possible, and has succeeded in about twenty drugs which are otherwise rather repulsive to the patient. The author finds the tablet the best and most convenient form of administration. He uses cocao butter and powdered sugar thoroughly triturated and compressed with the active ingredients in the tablet machine. The flavor should always be sprayed on the finished tablet with an atomizer. The most tasteless form of quinine is aristochin and the only sufficiently tasteless salicylate is salophen. Sabromin and sajodin are easily put up in the form of palatable tablets especially with the use of cocao. One objection against candy tablets is that children might poison themselves by eating too many at once. This objection can be easily overcome by prescribing only as many as can be taken at one time without danger.

6. **The X-Ray Treatment of Cancer.**—C. E. Skinner remarks that the *x*-ray is capable of exercising a powerfully curative influence over many cases of malignant disease and that its routine addition to extirpative measures will increase the number of curable cancer cases. It is impossible to tell beforehand which cases need röntgeniza-

tion and which do not, or which respond happily and which do not. There is reason to believe that many postoperative recurrences are more resistant to the *x*-ray than the original growth. It is easier for the *x*-ray to influence microscopic foci of malignancy than those of larger size; hence röntgenization should be begun as soon after extirpation as is consistent with the safety of the tissues involved in the operation wound and before recurrence has manifested itself.

7. **Cancer and Normal Tissue Ferments.**—By W. W. Hamburger. (See MEDICAL RECORD, Vol. 81, page 1165.)

8. **Acetonuria and Postoperative Vomiting.**—S. A. Chalfant concludes that vomiting occurs in a large percentage of cases after anesthesia. The liability to vomiting is increased when acetone is found in the urine. Protracted vomiting is best treated by sodium bicarbonate by the bowel and by lavage. The patients need careful watching on account of the liability to acid intoxication. Acetonuria is due to faulty metabolism and is increased by carbohydrate starvation. Acetonuria has no relation to the length of anesthesia. The duration of anesthesia has only a slight influence on vomiting.

9. **Treatment of Tubal Pregnancy.**—L. J. Ladinski pleads for a general recognition by abdominal surgeons of the dictum that hemorrhage into the peritoneal cavity must be sought for and checked as soon as diagnosed; that opening the abdomen of a patient profoundly shocked and anemic for abortion or rupture of a tubal pregnancy does not *per se* offer any graver risk than opening the abdomen for any other intraabdominal condition; and, furthermore, that delay in operating, no matter how slight, means increased risk, greater danger, and probably death to the patient. This plea is based on the study of 200 operative cases. The technique was practically identical in all. The abdominal incision was universally employed, the entire hand being introduced into the abdominal cavity and hemorrhage being checked by firm compression of the outer border of the broad ligament. In cases of extreme collapse, intravenous saline infusion was given simultaneously with the opening of the abdomen. In the 200 operations for tubal pregnancy there were three deaths, one following immediate operation in an unruptured tubal pregnancy, one following the third operation for ruptured tubal pregnancy, and one following the third operation for terminated ruptured tubal pregnancy with infection. In all of the immediate operations for ruptured tubal pregnancy there was no death. The author hopes to see the indication for immediate operation for ruptured tubal pregnancy accepted as the rule, as the fate of the patient depends on the promptness of the operation. He regards the operation as so free from risk that he feels justified in doing conservative surgery on the affected tube, when possible, although he recognizes the fact that the patient is thus subjected to a possible recurrence.

10. **Nephrotomy in Colon Bacillus Infection of Kidney.**—E. P. Davis discusses the treatment of colon bacillus infection of the kidney in pregnant women. A mixed infection with staphylococci and streptococci may co-exist. The symptoms are indefinite pain in the right abdominal and right dorsal region, much resembling that of subacute appendicitis. The pure culture of the colon bacillus can usually be obtained from the urine and blood examination shows a high leucocytosis. In mild cases the disease tends to recover on a milk diet and an abundance of pure water. Rest and free action of the bowels are essential. When infection becomes overwhelming, and is mixed, the kidney may be riddled with abscesses and pyemia and septicemia may follow. The medical treatment depends on a correct diagnosis between this infection and pyelonephritis, which diagnosis may be difficult or impossible. Fortunately the treatment for both conditions, if mild, is the same. If the condition does not yield to medical measures kidney drainage by nephrotomy is advised as safest for both mother and child.

12. **Diverticulitis of the Large Bowel.**—B. H. Z. Giffin. (See MEDICAL RECORD, Vol. 81, page 1165.)

13. **Treatment of Pulmonary Tuberculosis by Compression of the Lung.**—By M. E. Lapham. (See MEDICAL RECORD, Vol. 81, page 1166.)

15. **Rheumatism.**—E. Mingus advances the theory that in many cases of rheumatic fever the initial seat of infection is in the intestinal tract, from which the absorption of bacteria and their toxins occurs; on entering the circulation these cause peripheral symptoms in susceptible tissues. Chronic or recurring attacks are or may be due to the persistence of the bacteria of rheumatic fever in the intestinal tract in an attenuated condition and are aroused to activity by dietetic and hygienic errors of the patient which cause a reduction in metabolic activity and natural resistance.

16. **Transplantability of Malignant Tumors.**—J. B. Murphy describes his investigations which show that mammalian tumor tissue can live and grow actively in the chick embryo, although in the adult chicken it quickly dies and is absorbed. By transfer from one embryo to another the mammalian tissue can be kept growing continuously in the avian host for as long as forty-six days, and probably indefinitely. This proves that the mammalian cells are able to utilize the food supplied by the avian embryo. Whether the phenomenon is dependent solely on this factor, or whether the absence of a defensive mechanism in the embryo plays the more important part is a subject which is being studied and on which a report will be made later.

1. **The Origin of Life.**—By E. A. Schäfer. (See page 582.)

2. **The Albumin Estimation of the Spinal Fluid.**—J. G. Greenfield calls attention to a condition of the spinal fluid described by the French writers as the "syndrome of massive coagulation and of xanthochromia without cellular elements." This condition was first described in 1909 by Blanchetière and Lejonne in a case of tumor of the spinal dura at the level of the seventh to ninth dorsal segments. Massive coagulation and xanthochromia of the cerebrospinal fluid had been noted by Sicard and Descomps in 1908 as occurring in syphilitic meningitis, associated with a great increase in the lymphatic content. In one of the author's cases the tumor or compression was of a limited nature, but in two other cases the condition of the fluid might have been explained by transudation from a vascular tumor infiltrating the meninges widely. The occurrence of a similar fluid in cases of cerebral tumor, as reported by Quincke and Vincent, indicates that the damming up of the free circulation of the fluid has much to do with the production of an albuminous yellow fluid in the portions of the subarachnoid space shut off from the ventricles, as it is very possible that in these cases the foramen magnum was plugged by the downward pressure on the brain stem forming the so-called "pressure cone." Whether this condition is compatible with life for a period long enough to allow the spinal fluid to undergo such changes is, of course, doubtful, but this hypothesis harmonizes with the other

causes—spinal tumor, syphilitic leptomeningitis, etc. The yellow coloration seemed to be similar to what was found in cases of cortical hemorrhage, but a full chemical examination was not carried out in any of the cases. French writers have examined the fluid in many cases of fracture of the skull, cortical hemorrhage, etc., where this yellow coloration was present. Bard and Sicard consider it to be due to a special decomposition of the hemoglobin of the blood. Gilbert and Hersher, Fuffier and Milian, on the other hand, consider it to be due to a pigment, serochrome, normally present to greater or less extent in the blood.

3. **The Quantitative Cutaneous Tuberculin Test.**—E. C. Morland employs for this test the following dilutions of old tuberculin: 64, 16, 4, and 1 per cent. The most convenient scarifier is the platinum spade used by von Pirquet. The skin of the forearm over the brachioradialis muscle is rubbed with alcohol; the scarifier is held vertically between the thumb and forefinger, and with it four circular holes are drilled in the skin about an inch apart by a rapid twisting movement of the instrument on its long axis. The base of the pits should show vivid pink, but should not actually bleed. The dilutions of tuberculin are made with the usual diluent of ½ per cent. phenol in normal saline. A drop is now applied to each scarification in turn, the weakest dilution distally (nearest the hand), so that a stronger solution shall not be carried by the lymphatics to a proximal spot. The excess of fluid is sopped up with tiny pieces of sterile wool and the moist spots are left to dry for five minutes or so. The sleeve is then gently replaced and the patient is instructed not to wash the forearm until the next day, to avoid rubbing or irritating it, and to present himself for observation after 24 and 48 hours. The diameter of the resulting papules is measured in millimeters after 24 and 48 hours and the measurements are charted. Only the papule is measured, not the surrounding zone (if present) of hyperemia, and the diameter of the scarification is subtracted as irrelevant. The figures are charted as shown in a table and the resulting values of papule-size (5½) and papule-difference (3¼) are looked for in the table, where they are found to correspond to a sensitiveness value of 130 expressed thus: q P = 130. The sensitiveness value is really the inverse of the lowest strength of tuberculin which just gives rise to a reaction. Thus, if 5 per cent. be this strength, 100/5 or 20 is the sensitiveness value; or if 1 per cent. tuberculin just gives a reaction, q P = 100. The application of the determination of q P in practice is: (1) in the deciding of the question whether an existent tuberculosis is in such a condition as to require treatment—what may be called the clinical diagnosis of tuberculosis; (2) as a guide to the progress of a case—if favorable, q P soon falls below the crucial limit; (3) in concluding or excluding the presence of tuberculosis in disease or ill-health where the diagnosis is doubtful—*e.g.* in bronchial asthma, bronchiectasis, enlarged glands, etc.; (4) in determining the initial dose of tuberculin for a therapeutic course (where q P is high and the sensitiveness accordingly great, a small dose should be chosen to begin with); and (5) in standardizing any particular preparation of tuberculin and comparing two or more preparations. In drawing a conclusion from the value of q P certain points should be borne in mind: (1) the Pirquet reaction tends to disappear in advanced cases of tuberculosis and in miliary tuberculosis of rapid course; (2) it is constantly absent during the first ten days of measles and in some other transient acute conditions; (3) q P tends to remain high long into convalescence from bone and glandular tuberculosis, and (4) in the negative phase of a tuberculin inoculation q P may be very high, but it is remarkable how rapidly the large papules disappear as the positive phase sets in.

4. **The Treatment of Flatfoot.**—P. B. Roth describes a treatment for this condition in which the use of arch springs or sole plates is dispensed with The treatment consists of: Attention to footwear, attention to position in standing and walking, and regular daily exercises. (1) *Attention to footwear:* Whether boots or shoes are worn, whether they button or lace, they must be the shape of the feet. If this primary essential is not secured the whole treatment may as well be abandoned. If the degree of flatfoot be anything more than the merest trace, mechanical means are utilized to throw the weight of the body, distributed down the leg, slightly outside the center of the ankle joint. This is effected by thickening the sole and heel of each boot along its inner side by one-fourth, one-third, or one-half inch, the amount depending upon the severity of the case; the worse the case the greater the thickening. The additional leather is in the form of a wedge, with its base to the inside and its apex to the outside of the foot, so that the extra thickness on the inside fades off to nothing on the outside. Not only does it fade away outward toward the outside, but also forward toward the tip of the shoe, from a point situated about an inch behind the tip. (2) *Attention to position in standing and walking.—Standing:* The patient must always stand on both feet, with the toes slightly turned in and the heels slightly turned out. He must never stand with the toes turned out, or on one foot to rest the other. Every now and then he must raise the heels just clear of the ground, that is, stand on the toes sufficiently to bring all the muscles of the foot into action. Whenever the feet begin to ache he should do this. In addition, he should stand with the feet very slightly turned over on their outer border. *Walking:* He must walk with the feet pointing straight forwards—never with the feet turned out. (3) *Regular daily exercises.*—The exercises, to be done the first thing every morning, preferably with the shoes off, are two in number: (*a*) Standing, alternately raising heels and toes. To steady the body, both hands touch the mantelpiece or wall. The heels are slowly raised from the ground and slowly lowered, then the toes are slowy raised and slowly lowered, the exercise thus consisting of four distinct movements. The feet are kept slightly turned in and slightly turned over on their outer border all the time. The exercise is repeated from 50 to 100 times. (*b*) Sitting on one chair, with the foot projecting over the edge of another, the calf of the leg resting on the seat. Keeping the knee still, the foot is slowly circumducted to its full extent in all directions, down, in, up, out, fifty times; then down, out, up, in, fifty times. By means of this treatment it is possible to cure flatfoot without the use of arch supports.

Erythema Nodosum, Associated with Mammary Tuberculosis.—F. Parkes Weber reports the case of a rather delicately built woman, aged forty-seven, who had previously had no serious illnesses, and had apparently enjoyed good health. She was admitted to the hospital April 6, 1912, suffering from a chronic swelling in the right breast of at least two months' duration, which had not caused her much pain. This was excised on April 9, and found to be tuberculous, the microscopical sections containing many characteristic giant cells of the tuberculous type. On admission she was likewise suffering from florid erythema nodosum affecting both legs up to just above the knees, and there was a little pyrexia. The erythema nodosum, which had commenced about March 30, almost completely disappeared by the end of April. The patient had not been taking any drug, such as potassium iodide, which might be supposed to be connected with the onset of the erythema nodosum. There was no history of syphilis. She had had twelve children, nine of whom were still living, and no miscarriages. A good deal of attention had been given, especially on the Continent, to the occasional association of erythema nodosum with tuberculosis, a connection which had been recognized and described by Landouzy in 1907.—*Proceedings of the Royal Society of Medicine.*

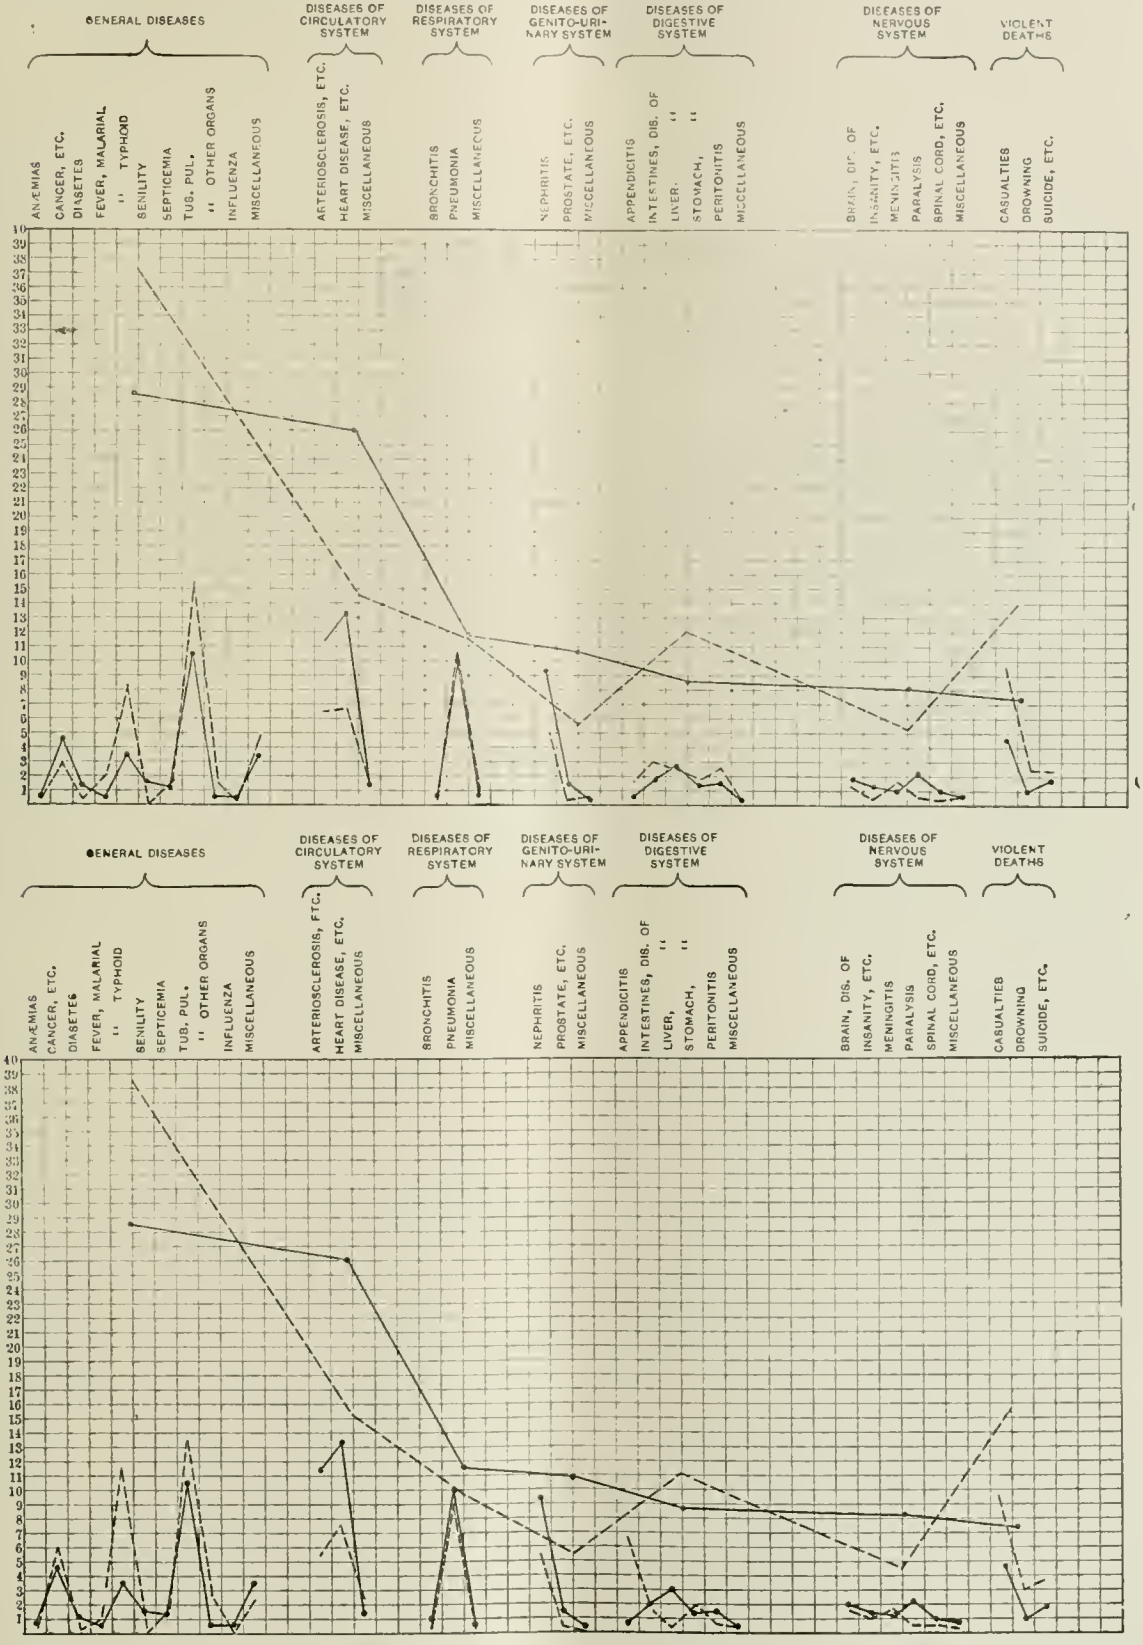
Insurance Medicine.

CAUSES OF DEATH IN THE FIRST FIVE YEARS OF INSURANCE.

To the Editor of the Insurance Department:

Sir:—I have been reading over the Medical Record of May 4, particularly the remarks on "Mortality and Causes of Death in the First Five Years of Insurance." I noticed the conclusions from Florschutz and it has occurred to me that you might be interested in the experience of this company along somewhat similar lines.

The tables differ somewhat and in order that you may read them intelligently you should know how they are built up. In 1910 I went over all the deaths which had occurred in our company since its beginning, making a separate heading for each



cause of death which was responsible for half of 1 per cent. or more and bunching the others under a subheading of miscellaneous. The continuous line represents this average, the dotted lines the par-

ticular class under discussion. I am sending two charts, one of all deaths occurring with a duration of five years or less, the other deaths which occurred on policies written between 1904-1910.

The percentages referred to are percentages of the whole. For example, you will notice that during the whole history of the company 10½ per cent. of our deaths has been due to pulmonary tuberculosis. In all of our business with a duration of five years or less 15½ per cent. has been due to tuberculosis, while in our more recent business, 1904-1910, we had 13.75 per cent.

The upper line represents deaths by groups, that is, in the history of the company, 26 per cent. of our business has been due to disease of the circulatory system divided into arteriosclerosis, etc., heart disease, etc., and miscellaneous. On business written 1904-1910 15 per cent. was due to that cause.

E. W. Dwight, M.D.,

Medical Director, New England Mutual Life Insurance Company.

The Relations of the Medical Examiner to the Company.—W. S. Kendrick says that no position requires that its holder be distinguished by a greater number of virtues than that of medical examiner for life insurance. He must, of course, be a graduate physician, licensed by the State: must have had some experience in private practice; finally, his character, financial standing, morality, habits, etc., undergo a close scrutiny before he is considered for appointment. When accepted, his work is carefully scrutinized and graded, and he is promptly dropped if his record proves unsatisfactory to the company's officers. Kendrick says that he, as a medical director, has to deal with two kinds of examiners: those who do good work and those who do not. Many examiners think that the companies themselves make light of the medical examinations and would rather not know too much about an applicant in order not to be compelled to exclude him. Others are quite indifferent to the work, and lose the educational opportunity afforded by the task of finding hidden pathological conditions in supposedly normal individuals.

The object of examination is, of course, to eliminate such persons as have, or are likely to develop, some disease which would render the risk prohibitively hazardous. The part of the examination blank reserved for questions and answers may give a hint of just such condition and should be carefully filled out, the meaning of any obscure questions being explained to the applicant. The medical director considers this part of the blank of as much value as the results of the physical examination, and any further inquiries from him about the matter should be promptly answered. Delay should not be tolerated, for the agent may suffer, because of the activity of other agents or of total change of heart in the applicant.

Of course, physical examination must be honestly made. Kendrick has known of numerous blanks in which such data as uranalysis, weight, height, condition of the heart and lungs were never properly obtained but simply "faked." Of course, some work of this kind may remain undiscovered, but sooner or later the morally deficient examiner gets caught.

Superficial examinations are worse than valueless, for they are responsible for much of the losses sustained by the life insurance companies during the first few policy years. Deaths from tuberculosis and from heart disease within a few months of insurance reach a total which is a reproach to the medical profession. Weight and height must be accurately determined and not guessed at, for it must be remembered that weight alone can disqualify an applicant. The lungs should be carefully examined, the chest being bared and stethoscope being used. Any objections to baring the chest should always be viewed with suspicion. The temperature should be always taken, and the pulse counted. The heart must not be examined with clothing unremoved, and the arteries should be palpated carefully. Blood pressure estimations are invaluable and will soon be required by all companies. Urine for examination should be voided in your presence, for substitution has been practised in too many instances where this precaution was not taken. Uranalysis should be carefully performed. In Kendrick's company, of the cases rejected for abnormalities in the urine, only 10 per cent. were reported unfavorably by the examiner; the rest were excluded because of the findings by the chemist in the home office.—*The Lancet-Clinic*, August 17, 1912.

Refusal of An Injured Person to Submit to Operation as Contributory Culpability.—The Imperial Court has repeatedly ruled that it shall be demanded of an injured person, in order that he may recover, that he make use of all the resources of medical science tendered to him, so far as he is able. This obligation may include operations, not of course according to any standard or precedent, but dependent on the exigencies of his particular case—the character of the injury, the severity and danger of the intervention, etc., and, in general, the outlook for recovery. Thus in a particular case the lower court having decided that an injured man's obligation was to have a joint of a finger amputated, the Imperial Court concurred. The operation would not have been severe or dangerous, and there would have been no impairment of the earning capacity and the complainant could well have afforded the expense of the operation. The urgency for the intervention must also be gathered from the fact that the attending physician refused to continue with the case unless the operation was performed. Hence the lower court ruled that patient's refusal to be operated on amounted to contributory neglect. This decision affects the status of a damage suit although it does not bear on the claim for insurance.—*Zeitschrift für Versicherungsmedizin*, July, 1912.

Insurance Larger by $400,000,000 Than Last Year.—During the year 1911, according to the *Insurance Press*, $502,640,000 was paid out by life insurance companies of the United States and Canada. There was an increase in the life insurance business during the year, a total of $3,000,000,000 in policies having been written and revived by the regular companies, or an excess of about $400,000,000 over the business of 1910. A total of $71,000,000 was paid out in New York State to policy holders, of which the sum of $25,138,562 was distributed in New York City alone. To Brooklyn went $7,954,750; Buffalo $2,215,000; to Rochester $1,094,000, and Albany $1,334,290. In New Jersey the sum of $16,500,000 was paid on policies.

Accidents in the Brewing Industries.—In the German Trade Associations there are 43 accidents for every 1,000 workmen, but in the brewing industries, 109. In the mines in Upper Silesia, there are 90 accidents to the 1,000, as compared with 119 in the breweries in the same district.

Book Reviews.

Lateral Curvature of the Spine and Round Shoulders. By Robert W. Lovett, M.D., Assistant Professor of Orthopedic Surgery, Harvard Medical School; Associate Surgeon to the Children's Hospital, Boston; Surgeon to the Infants' Hospital, Peabody Home for Crippled Children and Massachusetts Hospital School, Canton; Member of the American Orthopedic Association; Korrespondierendes Mitglied der Deutschen Gesellschaft für Orthopädische Chirurgie; Socio della Società Italiana di Ortopedia. Second Edition, revised and enlarged, with 171 illustrations. Price, $1.75 net. Philadelphia: P. Blakiston's Son & Co., 1912.

In this edition of Dr. Lovett's well-known work several parts have been rewritten in order that it might keep pace with the recent progress made in this subject, particularly with reference to etiology and treatment. The author's method of forcible correction of structural scoliosis is presented in satisfying detail. Considerable space is given to the subject of gymnastics and symmetrical exercises in the treatment of functional scoliosis. With regard to the relation of scoliosis to school life the author notes that "it may be assumed as reasonable (1) that bad air, fatigue and school life under poor general conditions, (2) improper school furniture, and (3) twisted writing positions favor bad attitude, and that the more constantly they are in operation the more effective will be their result in producing bad attitude. In the same way unfavorable home conditions in the way of bad food, overwork, and insanitary surroundings depreciate muscular strength and favor bad attitudes." Former views on the subject of the relation of the school to the production of scoliosis have changed. The author agrees with other modern authorities that while on general principles unfavorable school conditions are a competent cause of faulty attitude (false scoliosis) and of slight grades of true scoliosis, these school conditions are not likely to be the cause of moderate and severe scoliosis. Dr. Lovett's book is one of the best on the subject and should be carefully read by all practitioners who treat children.

Krankheit und Soziale Lage. Bearbeitet von Prof. Dr. Alfr. Blaschko, Berlin; Dr. W. Fischer, Berlin; Schularzt Dr. M. Fürst, Hamburg; Stadtrat Dr. med. Ad. Gottstein, Charlottenburg; Prof. Dr. Felix Hirschfeld, Berlin; K. Landesgewerbearzt Dr. Franz Koelsch, München; San-Rat Dr. B. Laquer, Weisbaden; Prof. Dr. R. Lennhoff, Berlin; Generalarzt a. D. Dr. H. Meisner, Berlin; Prof. Dr. M Mosse, Berlin; Oberarzt Dr. J. Reiche, Hamburg; Dr. Wilh. Schallmayer, München; Prof. Dr. H. Silbergleit, Berlin; Hofrat Dr. Ad. Theilhaber, München; Dr. G. Tugendreich, Berlin; Priv.-Doz. Dr. G. Voss, Düsseldorf; San.-Rat Dr. W. Weinberg, Stuttgart; Geh Med.-Rat. Prof. Dr. E. Wernicke, Posen; Prof. Dr. Fr. Willicer, Berlin; Ministerialrat Prof. Dr. Fr. Zahn, München. Herausgegeben von Prof. Dr. M. Mosse, Berlin, und Dr. med G. Tugendreich, Berlin. Lieferung. Price 6 Marks. Munich: J. F. Lehmann's Verlag, 1912.

Disease and social condition are two concepts that modern studies have brought into close association. In no country has more attention been given to this subject than in Germany, in which, with its highly organized statistical bureaus and its numerous insurance offices under the auspices of the state, the opportunities for gathering data on the social aspects of disease are particularly good. The work under review will consist of three parts, of which the first has been issued. The contents of this part consists of the following: An introduction, by the editors, who survey the entire subject in its larger and historical aspects; "The Principles of Morbidity and Mortality Statistics," by Professor H. Silbergleit, director of the statistical bureau of Berlin; "The Home in Relation to Disease and Mortality," by E. Wernicke; "The Influence of Nutrition on Disease and Mortality," by F. Hirschfeld, and "Occupatiton in Relation to Disease and Mortality," by F. Koelsch. It is hardly necessary to point out that these articles have been written with the thoroughness characteristic of German authors. The writers have drawn upon a vast fund of information gathered in different parts of the world. A comprehensive bibliography accompanies each article.

Baby's Teeth to the Twelfth Year. By Albert Westlake, DD.S. New York and London: Mitchell Kennerley, 1912.

This is a small book written in the form of a friendly talk that may be read in less than an hour. One of the important parts emphasized is the prevention of dental decay in the offspring by judicious care of the mother before the child is born, particularly with reference to a suitable dietary and the elimination of wastes. The domains of medicine and dentistry overlap each other, and the successful and conscientious dentist should possess a good deal of medical knowledge. Without disparaging the extent of the author's medical lore, one may point out one of his few inaccuracies when he treads outside of his own technical sphere. He states: "five months before the child is born a most important development of its bowels —that of the large intestine, the colon, and the rectum— is taking place as the little body is forming." Not many physicians will agree with the author when he recommends that the infant's anal sphincters when tight should be regularly stretched by the insertion of soap, cotton tampons, or a vaseline catheter. There are many useful recommendations regarding the proper care of the teeth; thus, the tooth brush should be properly disinfected before and after use, and should be replaced by a new one at the end of two weeks. Recently a dental authority in England has advocated the use of a fresh tooth brush every day! Modern science is apparently not in sympathy with latter-day efforts to reduce the cost of living. In the page in the back of this book headed "diary for record" there is a line for the physician's autograph and one for the nurse's autograph, but there is none for the dentist's autograph. Why this omission?

The Healthy Baby. The Care and Feeding of Infants in Sickness and in Health. By Roger H. Dennett, M.D., Instructor in Diseases of Children in the New York Post-Graduate Medical School; Assistant Attending Physician to the Babies' Wards in the New York Post-Graduate Hospital; Chief of Clinic in the Post-Graduate Dispensary for Children; Fellow of the New York Academy of Medicine. Price $1.00 net. New York: The Macmillan Company, 1912.

The household book on the care of the baby has become a national institution. The physician in giving his instructions to the anxious mother is frequently confronted with what Dr. —— says in his book, sometimes to the discomfiture of the medical adviser, who may not have noticed the open book upon the dressing-table. No two of these books are alike; some of them differ widely in the views expressed, but most of them serve a useful purpose. Those that attempt to explain too much, that go deeply into the pathology and symptomatology of early life, are, however, apt to do more harm than good. Dr. Dennett has avoided this danger. His book is well written and may be easily understood by the average mother. Particularly worthy of mention is the simple method recommended for the artificial feeding of healthy infants. This method consists in the use of whole milk, diluted with water, and with the addition of malt sugar. One may not altogether agree with the statement that "there are no dangers in giving antitoxin in its present-day perfection, no matter how delicate the child may be." With this as possibly the only exception, the views expressed by the author are sound and practical. The typography with its marginal headings is an excellent feature. The book may be recommended as one that the physician may safely put into the mother's hands without fear that it will usurp his function.

Transactions of the American Pediatric Society. Twenty-third Session, held at the Lake Mohonk Mountain House, Lake Mohonk, N. Y., May 31 to June 2, 1911. Edited by Linnaeus Edford La Fétra, M.D. Volume XXIII. Chicago: American Medical Association Press, 1912.

Among the many valuable articles that form part of this volume may be mentioned the following: "The Fundamental Requirements of an Infant's Nutrition," by John Howland; "Ward Problems," by Francis Huber; "The Treatment of Sepsis in Scarlatina with Antistreptococcus Serum," by Matthias Nicoll; "The Treatment of Pertussis with Vaccine," by Edwin E. Graham; a series of articles on various phases of poliomyelitis, by R. W. Lovett, Henry Koplik, John Lovett Morse, Simon Flexner, and J. H. Mason Knox; "The Use of Malt Sugar and High Percentages of Casein in Infant Feeding," by John Lovett Morse; and "Albumin Milk as Contrasted with Other Milk Mixtures in the Treatment of the Diarrheas of Children," by Henry Heimann. The article on "Muscular Hypertrophy of the Pylorus in Infancy," by Henry L. K. Shaw and Thomas Ordway, with its series of excellent photographs and photomicrographs, is a model of its kind as a clinical and pathological study. This volume is a tribute to the high plane which has been reached by pediatrics in America.

Pellagra: History, Distribution, Diagnosis, Prognosis, Treatment, Etiology. By Stewart R. Roberts, S.M., M.D., Associate Professor of the Principles and Practice of Medicine, Atlanta College of Physicians and Surgeons, Atlanta, Ga.; Physician to the Wesley Memorial Hospital; formerly Professor of Biology in Emory College. With 89 special engravings and colored frontispiece. Price $2.50. St. Louis: C. V. Mosby Company, 1912.

The marked increase in the number of cases of pellagra in this as well as other countries has caused an increased interest in this disease, and especially in its etiology. Pellagra was first discovered and reported in America in 1864 by Dr. John T. Gray, of Utica, N. Y. A second case was reported orally at the same time by Tyler of Somerville, Mass. It is probable that the number of cases of pellagra in the United States has been increasing since 1890, and that the disease has existed in the United States since 1880. A map showing the distribution of pellagra in the United States shows its predominance in the Southern States—sporadic elsewhere. Figures given show that pellagra has originated and prevailed in 33 out of 49 States, including the District of Columbia. It is probable that there are 10,000 cases of pellagra in the United States at the present time. One of the striking features of the disease is that it affects women more than men. Probably a majority of the American pellagrins do not work in the fields, but practically all American pellagrins live in a rural area. The cause of pellagra is unknown and the nature of the disease is in doubt. The chapter on etiology is especially interesting and discouraging. He states as follows: "The history of pellagra in other countries for the past two centuries warrants the belief that the United States is facing a long period during which the disease will prevail and in which many thousand human beings will become its victims. Little children will yield themselves to its insinuating and mysterious grasp; strong men will become weak and no longer able to render service as citizens; its mark will be left on the offspring of pellagrin mothers; and especially through the Southern States its ravages and its memory will exist side by side in every rural community. It has already fastened itself on the spinal cord, and its poisons flow in the blood of probably as many as ten thousand human beings in the States to-day. American medicine has given to the race the serum for the treatment of meningitis and has discovered the insect carrier of yellow fever. There is reason to believe American physicians will finally settle the problem of the cause of pellagra by the discovery and the proof of the toxin or the parasite which causes the disease. The corn theory is a century old and unproved—the infection theory of Sambon is new and unproved. Until the cause is definitely known the wisdom of prophylactic measures is in doubt, and the hope of more satisfactory methods of treatment is delayed. In the language of the European physicians pellagra has appeared in America and no doubt in America the true cause of the disease will be discovered. The book is of peculiar interest in connection with the rapid spread of the disease in this country and, in connection with the excellent work of Dr. Niles on the same subject, recently noticed in these columns, should be read by all interested in the disease, especially practitioners living in the Southern States.

Oral Surgery. A Text-Book on General Surgery and Medicine as Applied to Dentistry. By Stewart Leroy McCurdy, Professor of Anatomy and Oral Surgery, School of Dentistry, University of Pittsburgh; Chairman of Section in Stomatology, American Medical Association (1910, 1911, 1912); Orthopedic Surgeon, Presbyterian and Columbia Hospitals, etc., Pittsburgh; Author of "Manual of Orthopedic Surgery," "Anatomy in Abstract," "Emergencies in Abstract," "Arthrosteopedic Surgery." With 228 illustrations. New York and London: D. Appleton and Company, 1912.

In turning the pages of this book one is particularly impressed with its completeness. Within the limits of one volume the entire subject of oral surgery is presented succinctly and at the same time with sufficient attention to detail. The book is intended primarily for the dental student. It is divided into two parts: the first, including the principles of general medicine and surgery, intended for the junior student; and the second part, for the senior student, including oral surgery proper. The large number of illustrations, including those of *x*-ray photographs, are particularly helpful in a work of this kind. The author has omitted nothing that may be of service to the dentist from the viewpoint of general pathology. The rarer conditions, such as acromegaly and leontiasis ossea are given ample attention, while the important subjects such as syphilis, tuberculosis and malignant disease are presented in fullest detail. The book may be recommended without reserve.

Anleitung zur Funktionsprüfung des Ohres. Von Dr. A. Sonntag und Dr. H. J. Wolff in Berlin. Mit einem Vorwort von Prof. Dr. G. Brühl. Pp. 69. Preis, marks 2.60. Berlin: Verlag von S. Karger, 1912.

This paper-covered monograph on functional testing of the ear is a brief résumé of practically all the methods used at this time in the diagnosis of middle- and inner-ear disease. A companion brochure on the diagnosis of intracranial complications of aural disease would be very welcome. There is need of emphasizing the value of exact functional tests; for carelessness in this matter often makes the preoperative diagnosis nearly a matter of pure guesswork. The paragraphs on the pointing reaction (Zeigeversuch) and on the differentiation of labyrinthine is well worthy of a careful perusal.
affections are somewhat inadequate, but the little booklet

Stomatology in General Practice. A Text-Book of Diseases of the Teeth and Mouth for Students and Practitioners. By H. P. Pickerill, M.D., Ch.B., M.D.S. (Birm), L.D.S. (Eng.). Hon. Stomatologist to the General Hospital, Dunedin; Professor of Dentistry and Director of the Dental School in the University of Otago. London: Henry Frowde, Oxford University Press, Hodder & Stoughton, 1912.

The increasing recognition of the importance of stomatology in general medicine as well as in dentistry accounts for the large number of volumes that have recently appeared dealing with this subject. One of the best of these is the present volume which throws a beam of light across the "somewhat ill-defined territory lying between medicine and dentistry, which to many practitioners is to a certain extent a *terra incognita*." The book correlates, amplifies and elucidates much of the information given in works on medicine, surgery, and dental surgery. The author emphasizes the importance of the general practitioner recognizing the part played by chronic infections of the teeth in the causation of secondary systemic and local disorders. Diseases of the mucous membrane and of the jaws are described from an etiological point of view and the treatment is indicated. The subject of the treatment of fractures of the jaws is covered in admirable and satisfying detail. The pathology and preventive and remedial treatment of dental disease are discussed in detail. The effects of systemic diseases upon the oral tissues, and the effects of oral sepsis upon systemic conditions are presented in accordance with the latest teachings on these subjects. The illustrations are especially helpful and are of a high order of artistic merit. The paper, typography, and binding are in keeping with the high standard established by the Oxford University Press.

Laboratory Methods. With Special Reference to the Needs of the General Practitioner. By B. G. R. Williams, M.D. Member of Illinois State Medical Society, American Medical Association, etc., assisted by E. G. C. Williams, M.D., formerly Pathologist of Northern Michigan Hospital for the Insane, Traverse City, Michigan; with an Introduction by Victor C. Vaughan, M.D., LL.D., Professor of Hygiene and Physiological Chemistry, and Dean of the Department of Medicine and Surgery, University of Michigan, Ann Arbor, Michigan. Illustrated with forty-three engravings. Price $2.00 net. St. Louis: C. V. Mosby Company, 1912.

A unique field is apparently occupied by this book. It should prove exceedingly useful to the general practitioner who in most instances has been weaned from doing his own laboratory work owing to its supposed difficulties and complexities. In this volume there are presented in simplified form all the important methods of laboratory diagnosis. These simplified methods apply as well to apparatus as to technique. It is shown how five dollars or less will buy everything necessary for a physician's bacteriological laboratory, excepting the microscope. One of the interesting features of this book is the series of photographic illustrations showing the apparatus assembled for different kinds of laboratory work, as for bacteriological, blood, urinary analyses, etc. The chapter on detection of the common poisons is a valuable addition to this work, as is also the chapter discussing the relative merits of the diazo and Widal reactions. Other excellent chapters are those entitled "Every Day Stool Tests," "The Technique of Private Post-mortems," and "To Find the *Treponema pallidum* in Six Minutes." The book may be recommended to the general practitioner as a safe guide, and of even greater practical value than many of the larger works on laboratory diagnosis.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-Seventh Annual Meeting, Held at Baltimore, Maryland, May 28, 29, and 30, 1912.

The President, Dr. Howard A. Kelly of Baltimore in the Chair.

The Society met in the Assembly Hall of the Medical and Chirurgical Faculty Building, and after an address of welcome by Dr. William E. Moseley, of Baltimore, which was responded to by Dr. Brooks H. Wells, of New York, the reading of papers was begun.

Menstruation without Ovaries.—Dr. Palmer Findley of Omaha, Neb., reported a case in which both ovaries had been removed and the menstrual periods proceeded to recur at regular twenty-eight-day periods for one year and a half, at which time he opened the abdominal cavity and resected an adherent omentum from the fundus of the uterus and broke up numerous pelvic adhesions. He was then unable to find any trace of ovarian tissue. Seven months had intervened since this operation, and the patient continued to menstruate at regular intervals of twenty-eight days and in the usual amount. The findings in this case were almost identical with those in the case reported by Dr. George Gellhorn in 1907. The difference in the two cases was that the menstrual periods ceased to recur after Dr. Gellhorn excised the adherent omentum; while in the author's case the menstrual periods persisted. Gellhorn believed that the ovaries were not essential to menstruation and emphasized the important factor of added blood supply to adhesions to the uterus and the cyclic influence in determining the persistence of menstruation after the removal of both anatomical ovaries.

Dr. J. Clarence Webster of Chicago thought that all had had the experience of hemorrhage occurring after the removal of the ovaries; that they had even had the experience of hemorrhage occurring from the cervix after the removal of the body of the uterus. He believed that a considerable percentage of these cases in which the hemorrhage was irregular might be explained either by the vascular degenerations in the uterine or ovarian arteries or in both, or in varicose veins of the broad ligaments. He could only recall one case in his experience where a regular flow suggestive of menstruation occurred after castration. He did not believe that Gellhorn's suggestion of adhesions was explanatory in such cases. He thought the retention after the operation either of portions of the main ovary of the stump, or what was more likely, where good surgery was carried out, the existence of small portions (perhaps not even macroscopic) in the broad ligaments.

Dr. Henry T. Byford of Chicago emphasized the importance of the testimony of the patients. He recalled a patient in whom he removed the uterus and ovaries, and the woman said she continued to menstruate, but upon careful examination he found it was not exactly every month that this discharge began. The woman would have a little discharge between times. He told her to lie down a good deal, and if the discharge continued she was to return to see him. She would have a discharge of blood at one time at the end of three and a half weeks, at another time at the end of four weeks, and she was told to pay little or no attention to the little flow between times. There were a great many cases that were not menstrual in type, that is, they had not the menstrual periodicity. With regard to adhesions, he found in nearly all of his cases there were adhesions. He thought these adhesions could produce a discharge of blood. All had had cases of adhesions in which the chief symptom was hemorrhage. There was nothing more established in his mind than that adhesions interfered with the circulation by increasing it or damming it up, thus producing a bloody flow from the uterus, but this was not strictly menstruation.

Dr. J. M. Baldy of Philadelphia said he would like to emphasize not only the statement of the patient, but the statement of the doctor as to what was menstruation. The statement of the patient as regards menstruation was unreliable. He called attention to the statement, for instance, of a notable New York surgeon who transplanted ovarian tissue and called the discharge that followed menstruation. It was a mere show of blood which disappeared in a short time. It was not menstruation at all in the strict sense in which menstruation was recognized. When these patients told the gynecologist how long they menstruated, or how long they had stopped menstruating, it was found they all stopped for an unlimited length of time. He had never known a case go more than a year and a half at the outside; in a few cases the patients might have gone longer than that. They were not cases in which there were adhesions, and there was no considerable portion of ovarian tissue left to account for the continued menstruation, if it were a real menstruation in the individual case.

Dr. Frank T. Andrews of Chicago said that four girls were referred to him by a physician from Wichita, Kan., who had operated on one girl after marriage for a large ovarian tumor, he removing her ovaries. Another girl after some years of treatment he had likewise operated upon and removed her ovaries, and she had a normal change of life, with a normal result in that case, namely, stoppage of the flow. Then the family moved to Chicago and here were two girls suffering so severely with dysmenorrhea that, after caring for them and striving to avoid operation for several years, after having the best advice he could get from his gynecological and neurological friends, he decided to operate on one of them. Finally he did so and she made a normal recovery. The first one operated on improved very much for about nine months, but she kept on flowing apparently normally. The operation consisted in removing one ovary, leaving one ovary, and removing both tubes. After the dysmenorrhea returned, upon examination he found she had developed a year and a half after the first operation an ovarian tumor in the remaining ovary. He operated and removed that, and in carefully looking over the field he discovered there was a little stump he had not taken out on one side for some reason. He had not cut in and taken the whole tube out from the cornu of the uterus. So he removed that. The other one was thoroughly removed. He removed the tumor and she continued to menstruate. About three or four years later he removed the bulk of the uterus, leaving the cervix. The woman still continued to menstruate, and for somewhere in the neighborhood of four years, from that time until now, this woman went through exactly the same nervous disturbances every month that she used to go through while menstruating, but she had ceased to flow.

Dr. Edward P. Davis of Philadelphia pointed out that recent studies to settle the vexed question of the time of labor threw light upon the subject under discussion. It was found that the physiological life of woman consisted in periods of accumulation of blood terminating in increased pulse tension and in hemorrhage; that this condition was independent of the presence of genital organs, that is, the genital organs might be removed and this established physiological habit of woman still continued. In some cases the persistence of this discharge and increased pulse tension were the result of disorder of the ductless glands, and some cases were improved by the administration of thyroid extract or pituitrin or adrenalin. He thought this would explain some of the cases in the discussion where the absence of genital organs by operation had been followed by continued hemorrhage. The hemorrhage would occur from a physiological standpoint in any organ lined by mucous surface and richly supplied by subjacent capillaries, and in the absence of uterine mucosa hemorrhage was seen that was familiar also from the nasal cavity, sometimes from the gastric mucosa, and sometimes from the intestine, and rarely in the hemorrhages underneath the skin which had, when complicated by hysteria, given rise to those interesting cases of alleged bloody sweat and supernatal manifestations.

Dr. Clement Cleveland of New York City said he was reminded of a case he had some years ago where it was reported that both ovaries had been removed, and still the woman menstruated. It was a case in the Woman's Hospital in New York and his confrère, who had done the operation, had died in the meantime. The patient, therefore, came into his service, and he looked up the history. There was a miscarriage at the fourth month. The history showed that both ovaries had been entirely removed. He had very little faith in the functional activity of supernumerary ovaries, and he came to the conclusion that in most cases the discharge was due to a small portion of the ovary having been left behind. He was very positive it was in his case.

Dr. Seth C. Gordon of Portland, Maine, said he had reported two cases where pregnancy took place after as careful a removal of both ovaries as possible. One of these cases occurred in the practice of Dr. Chadwick, of Boston, who had assured him that he was certain he removed every particle of the ovary, and Dr. Gordon felt just as certain that he did likewise in his case, and yet both women bore one child each about a year and a half after the operation. He removed the ovaries of a young woman and she still continued to menstruate. Two years after-

wards he removed the uterus supravaginally and she still continued to menstruate. Two years later he removed the cervix and that stopped the menstruation, but menstruation was absolutely regular during the time that the cervix remained. So he believed that a physiological congestion actually occurred and that accounted for the regular menstrual period.

Chronic Cystitis of the Trigone and the Vesical Neck.—Dr. Edgar Garceau of Boston said that this condition was frequently incorrectly diagnosed as irritable bladder, or a neurosis of the bladder, etc. He referred to the significance of vesical psychoses. Neurasthenia was the consequence of obscure cystitis and not the cause of vesical symptoms. A clear urine with a red trigone might be symptomatic of severe cystitis. The absence of pus and blood did not exclude subepithelial cystitis. The cystoscopic appearances were referred to. There were two varieties of cystitis; one in which there was nothing to be seen but a red trigone, and this he called subepithelial cystitis, and the other in which there were marked pathological changes. Chronic cystitis of the trigone and vesical neck was always ushered in by frequent micturition. The writer was sure from long observation of these cases that the disease often started as a simple hyperemia of the trigone of the bladder, which had taken its origin in consequence of hyperemia of the pelvis which was due to some pelvic disease, and that the first symptoms were those usually experienced with vesical hyperemia. Perhaps the most serious feature of the disease was its long duration which entailed a severe degree of neurasthenia and reduced the patient to a pitiable state. In the cases in which the disease was submucous in character without superficial lesions, local treatment was not only of no avail, but harmful. A vaginal cystotomy must be performed and the top layer of the trigone dissected or curetted off through the diseased tissue.

The Use of the Continuous Fixed Laparotomy Sponge.—Dr. W. Francis B. Wakefield of San Francisco stated that as the matter of sponges was usually handled in the average operating room, it was quite remarkable that loose sponges were not closed up in the abdominal cavity oftener than they were. A sufficient number of surgeons throughout the country had used the continuous laparotomy sponge a sufficient length of time to prove conclusively that abdominal operations could be efficiently performed without the use of the dangerous loose sponge. This being so, it followed logically that as time went on and the knowledge of this fact became more widespread, surgeons would find it increasingly difficult to obtain, in courts of law, extenuation for having left a sponge in the abdominal cavity.

Dr. George Gray Ward of New York City said that for the past five years he had abandoned the use of separate sponges and had been using a continuous sponge in the form of a roller bandage, about three yards long and six inches wide, folded in four or five thicknesses of gauze. In his service no loose sponges were used in the abdomen. This roller bandage was unrolled as it was required, and the ends of it were tucked underneath the flanks, held back by the intestines and clamped to the laparotomy sheet.

Dr. I. S. Stone of Washington, D. C., stated that there were quite a number of cases on record where foreign bodies had been left in the abdominal cavity after operation, and why was it not proper for an individual, who trusted the surgeon to operate upon him or her, to grant the surgeon a carte blanche to do what was best and the patient accept the responsibility. It was about time for surgeons to take a stand with regard to operating upon free patients and doing free work in hospitals, and then possibly be sued for twenty or fifty thousand dollars, if they were worth that much, as a result. The profession had done very little to protect itself against suits of this character. It would seem to him that surgeons were at the mercy of the public, and especially of that class anxious to make the surgeon pay who had a good income.

Dr. John F. Thomson of Portland, Me., said the essential thing was the count of whatever was used in the form of sponges. This was applied at his private hospital in Portland to everything practically which possibly went through the abdominal incision in the operating room, the sponges being counted by two nurses, and counted before and after operation. Sponges might by accident be left, and he insisted on the count as being essential.

Dr. J. Wesley Bovée of Washington, D. C., said the plan he followed was to have a tape attached to each sponge that went into the abdominal cavity. If one used five or six sponges in the abdomen with a tape on each, he knew how many were put in and he knew when they came out. He would rather trust his own count than be responsible for the count of one or two nurses.

Dr. Brooks H. Wells of New York City stated that even the tape might go astray. In the only case he recalled in which a sponge was left inside the abdomen, the sponges were carefully counted before and after operation by a nurse, and they were all supposed to have tapes sewed on them with a weight on the end of the tapes. The patient, however, made a very good convalescence, but about eight or ten days thereafter she was brought into the clinic room and a sponge was removed from the culdesac.

Dr. George H. Noble of Atlanta, Georgia, said that sometimes in appendicitis cases he used a long strip of gauze, but when it came to the sponges he used one at a time, taking it out as soon as he put it in. There was a string attached to the sponge. This was the safest plan to follow in using sponges in the abdominal cavity.

Dr. Benjamin R. Schenck of Detroit, stated that the method they had followed at the Harper Hospital was to use large abdominal towels, using no sponges at all in abdominal operations. Some operators used gauze strips that were introduced into the abdomen, and these were numbered from one to eight, and the nurse must find every number.

Dr. Charles E. Thomson of Scranton, Pa., by invitation, mentioned a case in which, according to the records, no sponge had been used. There was no occasion to use one as it was a simple exploration, and yet a sponge was found later in the abdomen.

Dr. Frank T. Andrews of Chicago said he used small sponges which were carefully counted and carefully labeled with red marks. Sometimes he used a six-foot strip with a nickel ring attached to the end of a two-foot tape.

Dr. Brooke M. Anspach of Philadelphia had followed Dr. Clark's custom in the University Hospital, that is, to do all isolating by means of gauze taken from a long roll, using two or three thicknesses. The roll was probably four or five feet long, so that there was only one piece used to pack off the intestines and isolate the operative area. Twelve sponges were used for exposed bleeding points, and these were carefully counted, but as soon as bleeding ceased they were removed.

Gymnastic and Other Mechanical Means in the Treatment of Visceral Prolapse and Its Complications.—Dr. Franklin H. Martin of Chicago said that the treatment was based on the systematic reversal of the processes which caused or aggravated ptosis, including: (*a*) the placing of the patient regularly and at short intervals in the Trendelenburg position; (*b*) systematic, active, or passive exercise of the muscles of the abdomen, back, and chest, which were at fault as a result of ptosis, while the patient occupied the Trendelenburg position; (*c*) the prescribing and adjusting of properly designed temporary abdominal supports or corsets while the patient was in the perpendicular position; (*d*) proper instruction to the patient as to how to overcome the vicious habit of incorrect body attitudes often found in this condition, including exercise in the open air, diet, etc.

Dr. W. Francis B. Wakefield of San Francisco said he had been using a course of treatment for the last few years almost identical with that described by the essayist, and the results had been extremely satisfactory. Surgeons were shortsighted if they allowed some of these women, who advertised physical culture treatment in the popular lay journals, to treat this class of cases. One could take an intelligent nurse and train her to understand the principles of the application of such treatment and to make use of it intelligently, and it was better to take the necessary pains to do this and take these cases out of the hands of those outside of the profession and resort to a means of cure that would be very useful in the profession.

Dr. Charles P. Noble of Philadelphia said that these enteroptotic patients were part dead when they were going around. Their vitality was low. The treatment recommended by Dr. Martin gave them exercise and enabled them to eat more, and therefore, they developed more energy and were better. What they needed was rest. They should be fed abundant and wholesome food.

Dr. Clement Cleveland of New York City said the posture the essayist spoke about was not the Trendelenburg, but merely an inclined posture with the head downward. The Trendelenburg posture required relaxation not only of the abdominal muscles, but of the psoas muscles. In order to get this it was necessary to flex the thighs upon the pelvis with easy lifting, and the only table which did this was named after the speaker, it having been in existence for years.

Dr. Richard R. Smith of Grand Rapids said that when these women came to the gynecologist they came in a great majority of cases in a state of fatigue. A woman who was enteroptotic and in a state of equilibrium, who was leading a life within her strength, did not suffer at

all, but went about and did her work, and took her part in society with other women. She had a certain amount of vitality, but she gave out more easily. Then she consulted a gynecologist. The keynote was that she needed rest, both physical and mental. She needed to improve her nutrition, which meant better food, fresh air, or whatever other means might be employed.

Dr. William S. Stone of New York City said there were two specific details that had given him great satisfaction in connection with the treatment of these cases. He had found walking was one of the best forms of exercise. If the principles were carried out, it meant exercise and rest. A specific way of doing this was to tell the patients to take a walk and walk a little farther than they wanted to, and they should take the walk at such time that when they reached home, without doing any work, physical or mental, they were to lie down on the bed or sofa for the same length of time that was consumed in taking the walk. They should be trained to carry out regular exercises, which should be immediately followed after they get home by rest. In addition to that he relied in helping the circulation upon a good, brisk, careful rub.

Dr. Martin, in closing the discussion, said the treatment he had outlined was developed in connection with the treatment of surgical cases, in the treatment of kinks of the ileum, in the transverse colon, and in conditions that were operated for by Lane and for which he gained a considerable reputation. The treatment would relieve the Lane kink that was produced by ptosis. There was no question about this.

The Torsion of Tubal Enlargements with Reference Especially to Pyosalpinx.—Dr. Brooke M. Anspach of Philadelphia reported the case of a woman, twenty-six years of age, who entered the hospital with the clinical symptoms of acute appendicitis. Operation revealed torsion of the right tube and ovary. The tube was distended and filled with pus. The ovary was closely applied to the tube. The mass was purplish black in color and almost entirely free from adhesions. Tuberculosis was suspected as the underlying cause of the pyosalpinx, but the histological examination did not confirm the opinion. Two years later the patient returned for another operation and the left tube was found to be tuberculous. It was considerably enlarged and evidently represented the condition of the right tube before torsion had occurred. Histological examination showed typical miliary tubercles. The author then took up the subject of torsion of tubal enlargement in general and analyzed ninety-five cases which he collected from the literature. The variety of tuberculous enlargement which most frequently underwent torsion was a hydrosalpinx. Ectopic pregnancy and cysts originating in the tube itself and malignant tumors were other causes. There were twelve cases of twisted pyosalpinx reported in the literature. A considerable portion of these were proved to be tuberculous, and it was likely that tuberculosis was the cause of at least half of the reported cases.

The Influence of Myomata on the Blood Supply of the Uterus.—Dr. John A. Sampson of Albany, N. Y., stated that in fifty-two specimens colored injection masses were used, and in ninety-eight either the arterial or venous system was injected with a mass impervious to the *x*-ray. Stereoscopic radiographs were of great value in this work. All specimens were studied with a knowledge of the age of the patient, and before the menopause the exact stage of the menstrual cycle. The arterial and venous supply of the uterus and of myomata had been described in a previous paper. The influence of these tumors on the circulation of the uterus was of much greater clinical importance than the blood supply of the tumors themselves. Menstruation was found to be due to a venous flow and depended upon changes in the walls of the venous plexus of the endometrium, permitting the blood to escape. There were not any valves in the uterine veins, so that the amount of blood lost was regulated in a large measure by the efficiency of the uterus to hold it back, and especially its muscular efficiency. Large subserous myomata were very vascular and caused an hypertrophy of the uterine artery from which its nutrient vessels arose, and thus more blood was carried to the uterus and tumor; the excess over the normal was diverted to the tumor. The chief arterial and venous changes were in the peripheral zone of the uterus, and menstruation was usually not altered. Small intramural myomata were less vascular than the myometrium, and usually did not alter menstruation, but might possibly sometimes cause uterine insufficiency with its accompanying menorrhagia or metrorrhagia. Large intramural myomata were more vascular than the myometrium, but less vascular (venous). Submucous myomata represented a later stage of the intramural variety, and the veins over the surface of these were more apt to be affected than in the intramural variety. Adenomyomata did not necessarily disturb menstruation, and the endometrium over them was usually atrophied.

Relation of Thyroidism to the Toxemia of Pregnancy.—Dr. George Gray Ward of New York City summarized the present status of the toxemias of pregnancy of this type as follows: (1) That these cases may be classified into two groups: (*a*) Cases having no Graves' disease, but without sufficient thyroid secretion to promote the increased metabolism in the liver made necessary by the pregnancy, and probably due to the failure of the thyroid to hypertrophy. (*b*) Cases associated with Graves' disease, which condition usually caused serious disturbance in the metabolism. (2) Toxemias of the first group were frequently benefited by the administration of thyroid substance in the form of either dry extract or a serum. (3) In toxemias of the second group it was essential to determine whether the Graves' disease was in a condition of hyperthyroidism or hypothyroidism. In the former rest, applications of ice, milk diet, and sedatives should be employed, and if these measures failed an antiserum, such as the cytotoxic serum of Beebe and Rogers, should be administered. If the latter, thyroid substance should be given in the form of the dry extract, or, what was more efficient, if possible to obtain, a saline extract prepared from normal human glands, for hypodermic administration (4) Reliance should be placed upon nitrogen partition of the urine as a guide to the severity of the toxemia rather than on the blood pressure. (5) Induction of labor was very slow and uncertain in these cases, and where the history of former labors was that of dystocia elective cesarean section was probably the safest method of delivery for both mother and child.

Treatment of Acute and Fulminant Toxemia.—Dr. Edward P. Davis of Philadelphia said that each case of toxemia of pregnancy must be studied by a thorough physical examination, and that undue importance could not be assigned to any one symptom. One fact stood out preeminently in all fatal cases of toxemia of pregnancy, and that was the disorganized state of the blood, the minute hemorrhages in the liver and other organs, and in those patients in whom fulminant toxemia lasted for some time the occurrence of pulmonary edema and of gangrenous pneumonia. Whatever we could do in the way of treatment must be addressed to avoiding these conditions. The value of milk as a prophylactic diet must be insisted upon. The prevalent desire for fresh air should also be encouraged. A thorough physical examination should give warning of the approach of fulminant toxemia. Great variations in pulse tension, disturbance of the nervous system, inability to retain nourishment, disordered secretion and excretion, and variation in the nitrogenous output of the body, as demonstrated by the nitrogenous partition of the urine, were all of paramount importance. Should the conditions be unfavorable for spontaneous delivery and the uterus make an effort to expel its contents he believed that rapid delivery by abdominal section was the operation of choice. He preferred this to vaginal section because it was free from mechanical difficulties and did not open the veins above the pelvis and lower portion of the birth canal.

Treatment of Eclampsia.—Dr. Franklin S. Newell of Boston stated that, since the etiology of eclampsia was unknown, the treatment must be symptomatic and empirical. Until the physiological chemist found the causative agent treatment must be directed toward limiting the amount of the toxin which was absorbed in the first place; second, the prevention of damage by the toxin already absorbed; third, elimination of the toxin, and, fourth, treatment of the patient. Limitation of absorption of toxins was only to be accomplished by ending the pregnancy. The method of dilatation of the cervix and operative delivery must be chosen to suit the needs of the individual patient and operative skill of the obstetrician. Slow methods of dilatation were not to be advised. Damage by toxins already absorbed should be prevented and control of convulsions by the free use of morphia to the point of slowing respirations to 12 per minute. Lowering of blood pressure to approximately normal point by venesection serves to reduce the strain on the heart. As to the elimination of toxin, free catharsis induced by the use of saline and croton oil in repeated doses should be undertaken until several watery movements had resulted. The lower bowel should be washed out by colonic flushing. Probably most of the toxin was excreted by the intestinal tract, and if it was not removed might be reabsorbed and cause a recurrence of symptoms. The patient must be treated in certain cases and the disease allowed to care for itself, since it was evident in certain cases that any

active interference would cause the death of the patient, and the only hope lay in palliative means. In these cases and in patients who had reacted badly to operative procedures direct transfusion of blood should be considered as a possible life-saving procedure.

Dr. George Tucker Harrison of Charlottesville, Va., said that whatever be the nature and origin of the toxic substance which evoked the phenomena characteristic of eclampsia, two facts stood out in clear light. In the first place, the potency of the poison that produced the toxemia was made manifest by the degenerative changes in the kidneys, the anemia and hemorrhagic necroses in the liver, the hemorrhages into the brain, and multiple thrombosis. In the second place, the undoubted fact that, as a rule, the evacuation of the contents of the uterus was attended by a speedy relief of the symptoms—*restitutio ad integrum*. Bearing in mind these facts, it was logical to maintain that in cases of acute toxemia in pregnancy, whether with or without eclamptic attacks, the indication of treatment was to empty the uterus as speedily as may be. If the cervix was dilatable or dilated, either by manual dilatation or by the use of the metreurynter, but not by metallic dilators, sufficient dilatation might be obtained, so that version and delivery might be accomplished in a short time. Forceps should be applied only when the head was fixed in the pelvis. In a primipara, when the cervix was maintained in its entire length, the indication was vaginal cesarean section.

Treatment of Eclampsia.—Dr. Cyrus A. Kirkley of Asheville pointed out that prophylaxis was the more satisfactory treatment in the toxemia of pregnancy. Indefinite treatment was due to obscure etiology. Renal and hepatic insufficiency were probably the main etiological factors. Symptomatology was briefly discussed and the quantity of urea excreted rather than the presence of albumin determined the proper course of treatment. To eliminate accumulated toxins and to restore impaired or arrested function in the eliminative organ was the aim of treatment. Calomel and soda, followed by salines, alkaline diuretics, if not contraindicated, the hot pack, the hot air bath, glonoin, massage, pure air, and abundance of pure water were important aids in treatment. Venesection, if not contraindicated, both as a prophylactic and during and after the eclamptic seizure, was strongly endorsed. Chloroform and morphine were in disfavor. Veratrum viride was second only to venesection as an antieclamptic, but was in no sense a substitute. Decapsulation of the kidney had a doubtful place in the treatment of eclampsia, but thyroid extract might be useful as a prophylactic. The uterus should be emptied as soon as it could be done without increasing the risk to the mother. Should labor not begin with the first seizure and if the internal os uteri was obliterated dilatation and delivery by forceps or podalic version might be accomplished. The indications for cesarean section were pointed out, but too radical as well as too conservative treatment might result disastrously. While cesarean section should not be the *dernier ressort*, we should be absolutely sure that delivery by other means was impossible.

The Indications for and the Type of Operation to Select in the Toxemia of Pregnancy.—Dr. John O. Polak of New York drew the following conclusions: (1) That toxic vomiting which resisted rest, lavage, dextrose enemata, and enteroclysis, and presented a high ammonia ratio, or persistent acetone, a total white cell count of under 9,000, and a maternal pulse of 100 or more, should have the pregnancy interrupted. (2) Before the formation of the placenta the curette was the method of choice, and after this period anterior hysterotomy offered decided advantages. (3) The pre-eclamptic state, characterized by its high blood pressure, diminished urinary output, persistent albuminuria, etc., not yielding to dietetic, eliminative, and medicinal measures, justified evacuation, and surgical methods in skilled hands did less injury and had a lower mortality and morbidity than the less radical procedures. (4) When the convulsions and coma had occurred the termination of pregnancy improved the chances of the patient's recovery, and the method of delivery depended on the condition of the cervix, which determined whether it be by incision, bag, or nature, supplemented by version or forceps. Finally, anterior hysterotomy should always be the choice over manual dilatation when no effacement of the cervix had taken place.

Dr. Barton Cooke Hirst of Philadelphia had been using the parathyroid extract for five or six years, and he believed that in the rare types of toxemia he got better results than from the thyroid extract itself, but those toxemias that required parathyroid treatment were rare; they constituted only a small minority of the cases of toxemia seen in practice. He felt strongly opposed to Dr. Harrison's unqualified advocacy of the operative treatment, and he thought the society ought to carefully consider its responsibilities to the general profession. In the United States there were 7,500 cases of eclampsia every year, approximately. Of that number the vast majority were attended by the general physicians, and if the doctrine went forth from the society to the effect that the unqualified treatment of toxemia and eclampsia was the operative treatment it would do a vast deal of harm.

Dr. Richard C. Norris of Philadelphia stated that his last thirty cases of toxemia occurred during the period when vaginal cesarean section had been discussed by the profession. Of these cases there were thirteen actually eclamptic women who had had forty-two convulsions; there were seventeen pre-eclamptic cases past the seventh month of pregnancy. This group of cases was treated by the conservative plan—cases that in his judgment did not require the aggressive operative methods, yet one woman died without eclampsia from a widespread accumulation of fluid in the serous cavities, chronic Bright's disease, and none of the infants died, most of them being premature. He felt sure if he had subjected every one of these women to vaginal cesarean section he would not have had better results. He believed the time had come for us to attempt to study individual cases and properly classify them.

Dr. J. Whitridge Williams of Baltimore said that when it was essential to empty the uterus for vomiting of pregnancy vaginal hysterotomy or cesarean section was the method, and he had employed it for some years. As to the method of emptying the uterus in cases of eclampsia it was very essential to individualize, but he believed in every case where the cervix was rigid and where prompt delivery was necessary vaginal cesarean section was the operation of choice. He had employed this operation in a large number of cases with great success and great operative satisfaction.

Dr. Charles M. Green of Boston said that if we were going to be of the greatest service to womankind in this matter of pregnancy toxemia steps must be taken to get at the cases early. He happened to have had considerable experience this winter as the result of a pregnancy clinic they had been running in Boston since a year ago last May, and the result had been a considerable diminution in the number of cases of actual eclampsia, that is, women who went on to the point of having fits. They got these patients in all periods during pregnancy, not only when they presented themselves at the clinic, but when found by the visiting nurse, who was sent to keep track of these women when they presented symptoms of toxemia of pregnancy. As the result of this work they had had no cases of eclampsia. He did not mean to say by that that none of them had to be delivered or had not been delivered, but they had found by putting these patients under the usual eliminative treatment very often labor began and they delivered themselves and recovered without ever having convulsions, so that he was firmly of the belief that we should get better results, less actual eclampsia to treat, if we took steps in our clinics to get control of these women early.

Dr. Henry D. Fry of Washington, D. C., said he was never satisfied to empty the uterus until he had tried one remedy which had served a good purpose in the treatment of the early stage of eclampsia. After putting the woman to bed and prohibiting all food by the stomach and giving nutriment enemata he used inhalation of oxygen, and if he could not stop pernicious vomiting he was satisfied he should empty the uterus. He had made it a routine practice in the later months of pregnancy to examine the thyroid glands of all women, and if they did not have physiological enlargement of the thyroid at that time, if they had restlessness, sleeplessness, indigestion, he put them on thyroid extract, and had seen the symptoms disappear. He had seen the nitrogen output increase, and this did good in a certain class of cases.

Dr. George W. Kosmak of New York City said the term eclampsia was a misnomer in the class of cases to which it was generally applied. We had called a disease entity the toxemia of pregnancy by one of its prominent symptoms, but in a great many cases this prominent symptom did not appear. There were a great many cases of toxemia of pregnancy in the late months that did not have convulsions; some of them got over the toxemia and some of them terminated fatally. At a meeting held in Atlantic City several years ago Dr. Welch showed specimens from a series of four cases. They were brains and livers from each of these women, two of whom had convulsions and died as the result of toxemia, while the other two never had any convulsions, but passed meconium. Therefore, it was not fair in the treatment of these cases to assume

that convulsions were the deciding factors, and this was why he personally objected to basing a series of statistics on the presence of convulsions.

Dr. Hugo Ehrenfest of St. Louis referred to venesection in the treatment of eclampia and pregnancy and said it was an interesting fact that of late venesection had been suggested and recommended by many men. Many of these cases, he thought, were spoiled by the introduction of saline solution. One never knew when saline solution might prove detrimental to the patient, but the withdrawal of a large amount of blood worked approximately the same way as forcing delivery. According to investigation the true effect and force of saline solution lay in the loss of blood. No matter what method of treatment was resorted to in these cases the patient should be put into a hospital, and all statistics based on hospital experience in treating these cases. This should be one of the first points in any therapeutic effort. The majority of patients suffering from the toxemia of pregnancy could be brought into a hospital. He thought it was unsafe to resort to operative measures amid unfavorable surroundings. Conservatism should always be kept in mind in dealing with this class of patients.

President's Address: History of Vesico-Vaginal Fistula.—Dr. Howard A. Kelly of Baltimore pointed out that the ancients confused all forms of inability to retain the urine under the common heading of "incontinence." He said that Felix Plater in 1597 discussed the condition with the utmost clearness, but had no remedy ready to propose. The first great light upon the subject was found in the work of von Roonhuyse in 1663, describing a method of posture, exposure, denudation, and closure by means of a quilt suture. After paying his respects to Sims and Emmet, the speaker went on to discuss the newer dissection and flap-splitting methods of treatment other than those of direct denudation of the margins of the fistula, dwelling particularly upon the work of Hayward, Pancoast, Colles, Blasius, Mackenrodt, Walcher, and their followers.

Radical Abdominal Operation for Cancer of the Cervix Uteri.—Dr. John G. Clark of Philadelphia spoke on the radical abdominal operation for cancer of the cervix uteri, based upon forty operations.

Dr. Reuben Peterson of Ann Arbor spoke of the primary and end results of fifty radical abdominal operations for cancer of the uterus. There were ten deaths in the fifty-one cases, or a primary mortality of 19.6 per cent. His operative experience with the radical abdominal operation began some ten years ago, and until he had acquired some familiarity with the technique the results were very discouraging. This was shown by a primary mortality of 42.8 per cent. in the first fourteen cases. In the last thirty-seven cases there were but four primary deaths, a mortality of 10.8 per cent. In forty cases of carcinoma of the cervix there were nine deaths or a primary mortality of 22.5 per cent., while there was only one primary death in eleven cases of cancer of the fundus, or a mortality of 9 per cent. He had made a summary of the fifty-one cases which showed that eight patients with carcinoma of the cervix had died from recurrence of the disease, while one died of tuberculosis. Two patients with carcinoma of the cervix had had recurrences, but were still living. One patient had a recurrence in the vaginal vault five months after the operation. Indurated tissue about the size of the end of the thumb was removed at a second laparotomy. From personal examinations of seven patients out of the eleven with recurrences, he was able to say that in these the disease undoubtedly returned in the vaginal cicatrix. There were ten recurrences among the thirty-one cases of carcinoma of the cervix surviving the operation, while there was only one recurrence in the eleven cases of carcinoma of the fundus.

The Radical Abdominal Operation for Carcinoma of the Cervix, with a Report of Twenty-eight Cases.—Dr. Howard C. Taylor of New York City drew the following conclusions: 1. The primary mortality of the radical abdominal operation was not such that it should deter us from doing the operation. 2. The percentage of operability of the cases that came under the observation of an operator would be greatly increased by means of this operation over the simple hysterectomy as formerly done. 3. The end results would never compare favorably with the end results reported from abroad until we were able to get our cases at an earlier stage of the disease, and that our justification for doing a radical operation was its moderate mortality and the relief of symptoms in a disease otherwise hopeless. 4. That our most promising field of endeavor on the subject of carcinoma of the uterus should be: (*a*) More reliable and complete statistics on operability, the community operability, primary mortality, and end results. (*b*) A well regulated organized plan of campaign in order to get the cases earlier than we do at the present time by furthering the education of the medical profession, and the public at large and by the routine examination of all women after a certain age.

The Prognosis in Radical Abdominal Operations for Uterine Cancer.—Dr. Fred J. Taussig of St. Louis said the radical abdominal operation for cervical cancer was not in itself a dangerous procedure. It became dangerous only in advanced cases, owing to the attendant complications, septic infiltration, injury to the bladder or ureter, bleeding, and prolonged narcosis. The percentage of recurrences was distinctly less after this operation than after simple vaginal hysterectomy. It should be employed in every case of cervical cancer in which there was no special contraindication to a more extensive operative procedure. In far advanced cases the immediate operative risk was so great and the likelihood of recurrence such that these patients had better be classed as inoperable. Out of fifteen patients in his group not a single one was alive today. Only by improving the training of the average practitioner, by the extermination of quacks and most of all by the persistent systematic education of the laity could we ever hope for better results.

Remote Results in Abdominal Hysterectomies for Cancer of the Uterus.—Dr. Thomas S. Cullen of Baltimore said he had performed in all over fifty Wertheim operations. The more recent ones he did not refer to in his tabulation. He reported the result in forty-eight cases. Immediate deaths, eleven cases; remote deaths at periods varying from a few months to five years, twenty cases; patients lost track of, five cases; patients living and well at periods varying from one to thirteen years, twelve cases. Twenty-five of Dr. Cullen's cases had been operated upon over five years with the following results; the mortality in the first twenty-five cases was seven, or 28 per cent.; in the succeeding twenty-three cases, four, or 18 per cent. With the early detection of cancer the mortality would naturally be lower. Immediate death, seven cases; not located, one case; remote death at periods varying from a few months to five years, eleven cases; living and well, six cases or 24 per cent. In 24 per cent. of Dr. Cullen's cases operated upon over five years the patients were living and well.

Modern Methods of Treatment of Prolapsus Uteri.—Dr. E. E. Montgomery of Philadelphia said that prolapse might be simple or complicated. No surgical procedure was applicable to every case. Certain principles must be kept in mind on which any operative procedure must be based. Their purpose should be to reduce the size of the heavy organ, replace support, and antagonize or deflect intraabdominal pressure by correction or fixation of the position of the uterus. The operative procedure may be vaginal, abdominal, or both combined. The uterus may be retained or extirpated. In all conditions requiring severe and complicated measures, its retention should be associated with sterilization. After the climacteric in marked prolapsus attended with edema and gravity sores, hysterectomy was preferable as a procedure. In the majority of cases the vaginal route was the most satisfactory. In all cases the rectovaginal interposition of the levator ani muscles was of the greatest value.

Prolapse of the Uterus.—Dr. J. M. Baldy of Philadelphia said that plastic work alone would not cure a certain per cent. of cases. Consequently abdominal work of some kind was necessary in certain instances, but supplementary plastic work was always necessary. The abdominal work could be better and more surely done if the uterus was sacrificed than if an effort was made to retain it. In the class of cases in which this operation was performed the woman was past the child-bearing period and no sentiments in regard to the uterus need be wasted.

The Principle Involved in the Operation for the Relief of Procidentia Uteri with Rectocele and Cystocele.—Dr. J. Riddle Goffe of New York said the true principle in normal support of the pelvic organs in women conformed to that of the other organs, namely by suspension from above. Any operation for the relief of prolapsus with rectocele or cystocele that ignored this principle was false in conception and in the long run was doomed to failure. The universal maxim in plastic surgery was to discover nature's plan and conform to it. In child-bearing women the uterus was retained and restored to its normal position by the shortening of the uterosacral and the round ligaments. In cases of extreme procidentia, especially in women beyond the child-bearing period, the uterus was removed, but the deflected plane of tissue was maintained by stitching together the broad ligaments across the pelvis. The round ligaments were retained and still assisted in tilting this plane of tissue so as to deflect intraabdominal pressure as before. It was diverted from

its original direction where it would tend to force the contents of the pelvis out of the vagina. The other prominent feature of the operation was the restoration of the bladder to its normal position and function. A series of forty-four cases was presented in which the operation he described had been performed, the period of time elapsing since the operation extending from two to five years. On examination of all these cases it proved entirely satisfactory with one exception. Two cases had become pregnant and borne children at full term two years after operation.

Procidentia of the Uterus Treated by Plication of the Vagina and Conjoined Shortening of the Uterosacral and Broad Ligaments.—Dr. WILLIAM M. POLK of New York City pointed out that the purpose of the operation was to remedy the defects without removal of the uterus, ovaries or tubes. Two patients became pregnant subsequently and carried their children to term. Eight cases retained all the benefits two years from the date of operation. The bladder was separated from the vagina as far as the urethra. The entire anterior vaginal wall was then folded in by suturing the sides of the vagina together with kangaroo tendon. The uterosacral and base line of the broad ligaments were conjointly shortened by a ligature which encircled above the uterine artery and within the ureter the lower half of the broad ligament and the uterosacral fold. One-half an inch from the uterus for the broad ligament, and an inch from the uterus for the sacral fold. The sutures, one for either side, were drawn forward and passed deeply into the tissue of the uterovaginal region and tied. Kangaroo tendon suture material was used for the plication and for this shortening. Additional sutures were used to fasten securely the tissues brought forward from the broad ligament and uterosacral fold to make more secure the anchorage. The fold produced by the plication at the anterior vaginal wall was now incised from below, turning back excessive tissue, it being trimmed off only where necessary, and the surfaces brought together by through and through sutures. In this way a strong supporting column was given to the base of the bladder, the whole being swung by taking up the slack in the lateral vaginal attachments, and by shortening of the broad ligament and uterosacral that had been mentioned above. The operator had carried out the procedure on eighteen cases without any undue shock or hemorrhage, and with good recovery in each case.

Dr. HIRAM N. VINEBERG of New York described the end results with various operative procedures for procidentia uteri and extensive cystocele prior and subsequent to the menopause.

Operative Treatment for So-Called Functional Dyspepsia.—Dr. WILLIAM H. WATHEN of Louisville said that every case of continued or inveterate dyspepsia or dyspepsia disappearing and recurring at regular intervals was antedated by a pathology in some part of the body, but in the large majority of cases the lesion would be found in some abdominal viscus as the appendix, the gall-bladder, the stomach, the duodenum, the large or small intestine, or the uterine adnexa. Dyspepsia caused by appendicitis or gall-stones, with no stomach or duodenal adhesion, could be cured by the removal of the appendix, or by the removal of the stones and drainage of the gall-bladder and bile ducts. In gastric ulcer the lesion should be excised, or if this was not possible, it should be infolded by linen sutures introduced deep enough to include the blood vessels around the ulcer. The excision of a gastric ulcer was important because of the fact that 75 per cent. of the cases of carcinoma of the stomach had their origin in a chronic ulcer. As carcinoma was seldom, if ever, primary in the duodenum, the excision of the ulcer was not often indicated, as in ulcer of the stomach.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Henry C. Coe, New York City; *Vice-Presidents*, Dr. George H. Noble, Atlanta, Ga., and Dr. George Gellhorn, St. Louis, Mo.; *Secretary*, Dr. Leroy Broun, New York City; *Treasurer*, Dr. J. Wesley Bovée, Washington, D. C.

Washington, D. C., was selected as the place for holding the next annual meeting.

Chronic Edema of the Fauces and Larynx in a Boy.—H. Lack reports the case of a boy, aged twelve, in whom for nearly five years, the uvula had been as large as a finger. It was removed for microscopical examination, but merely showed round-celled infiltration. The stump of the uvula was thickened, the pillars of the fauces were edematous, the epiglottis was considerably swollen, and the arytenoids, especially the left one, were so edematous that they flapped about and looked like mucous polyps. Antisyphilitic remedies had no effect, and the diagnosis has remained in doubt.—*Proceedings of the Royal Society of Medicine.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

METHODS OF ORGANIC ANALYSIS. By HENRY C. SHERMAN, Ph.D. Second Edition. 407 pages; cloth; price $2.40 net. The Macmillan Company, Publishers, New York.

ANLEITUNG ZUR FUNKTIONSPRUFUNG DES CHRES. By Dr. A. SONNTAG and Dr. H. J. WOLFF. 69 pages; illustrated; paper; price 2.50 M. S. Karger, Publisher, Berlin.

STUDIEN ÜBER DARMTRÄGHEIT. By Dr. FRANZ XAV. MAYR. 276 pages; paper; price 6 M. S. Karger, Publisher, Berlin.

VORLESUNGEN ÜBER DIÄTBEHANDLUNG INNERER KRANKHEITEN. By Prof. Dr. H. STRAUSS. 429 pages; paper; price 8.60 M. S. Karger, Publisher, Berlin.

DIE PROSTATAHYPERTROPHIE. By Dr. WILHELM KARO. 50 pages; paper; price 1.60 M. Oscar Coblentz, Publisher, Berlin.

LABORATORY METHODS. By Dr. B. G. R. WILLIAMS, M.D., and E. G. C. WILLIAMS, M.D. 204 pages; illustrated; cloth; price $2.00 net. C. V. Mosby Medical Book & Publishing Company, Publishers, St. Louis.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. TWENTY-THIRD SESSION. Vol. XXIII. Edited by LINNAEUS EDFORD LA FETRA, M.D. 338 pages; illustrated; cloth. American Medical Association, Publishers, Chicago.

AN INDEX OF SYMPTOMS. Fourth Edition. By RALPH WINNINGTON LEFTWICH, M.D. 451 pages; cloth. William Wood & Company, Publishers, New York.

THE REGISTRATION AND SANITARY SUPERVISION OF PULMONARY TUBERCULOSIS IN NEW YORK CITY. By JOHN S. BILLINGS, Jr., M.D. 93 pages; illustrated; paper. The Department of Health, Publishers, New York.

LES ANTICORPS SYPHILITIQUES. By Dr. ALBERT TOURAINE. 211 pages; pager. G. Steinheil, Publisher, Paris.

CHEMISCHE METHODIK FÜR AERZTE. By Prof. CARL OPPENHEIMER and Dr. W. GLIKIN. 93 pages; cloth; price 2.40 M. Georg Thieme, Publisher, Leipzig.

REPORT FROM THE PATHOLOGICAL DEPARTMENT AND THE DEPARTMENT OF CLINICAL PSYCHIATRY, CENTRAL INDIANA HOSPITAL FOR THE INSANE, 1909-1910 AND 1910-1911. Vol. IV. 344 pages; cloth. Central Indiana Hospital for the Insane, Publishers, Indianapolis.

THE PRACTICAL MEDICINE SERIES 1912. Vol. I. GENERAL MEDICINE. Edited by FRANK BILLINGS, M.S., M.D., and I. H. SALISBURY, A.M., MD. 404 pages; illustrated; cloth; price $1.50. The Year Book Publishers, Chicago, Publishers.

THE PRACTICAL MEDICINE SERIES 1912. Vol. II. GENERAL SURGERY. Edited by JOHN B. MURPHY, A.M., M.D., LL.D. 616 pages; illustrated; cloth; price $2.00. The Year Book Publishers, Chicago, Publishers.

ORAL SURGERY. By STEWART LEROY MCCURDY. 469 pages, with 228 illustrations; cloth. D. Appleton & Company, Publishers, New York and London.

FATIGUE AND EFFICIENCY. By JOSEPHINE GOLDMARK. 890 pages; cloth; price $3.50. Charities Publication Committee, Publishers, New York.

OUTLINES OF EARLY DEVELOPMENT. By R. W. JOHNSTONE, M.A., M.D., F.R.C.S., M.R.C.P.E. 23 pages; illustrated; cloth; price 1/6 net. John Currie, Publisher, Edinburgh.

ELSIE LINDTNER. By KARIN MICHAELIS STANGELAND. 212 pages; cloth; price $1.20. John Lane Company, Publishers, New York.

THE PREVENTION AND TREATMENT OF DISEASE IN THE TROPICS. By EDWARD S. CRISPIN, M.R.C.S., L.R.C.P. 95 pages; cloth; J. B. Lippincott Company, Publishers, Philadelphia, Pa.

THE HOSPITAL CORPS QUIZ COMPEND. By FRANK C. GRIFFIS, M.D. 218 pages; cloth. The Edward T. Miller Company, Publishers, Columbus, Ohio.

THE NON-ANTIGENIC PROPERTIES OF LIPOIDS EXTRACTED FROM HUMAN LIVERS WITH A METHOD OF PREPARATION OF ANTIGEN FOR USE IN THE WASSERMANN REACTION. By J. G. FITZGERALD and J. B. LEATHERS. 46 pages; paper. University of California, Publishers, Berkeley.

LES SPOROTRICHOSES. By DE BEURMANN and GOUGEROT. 852 pages, with 161 illustrations in the text and 8 plates; paper; price 20 francs. Librairie Felix Alcan, Publishers.

THE CLASSICAL PSYCHOLOGISTS. By BENJAMIN RAND, Ph.D. 734 pages; cloth. Houghton Mifflin Company, Publishers, Boston.

Miscellany.

THE MEDICAL HONORARIUM.

It is hardly to be expected that at this late day anything new can be written about the medical fee. What renders extremely difficult any discussion about the latter is the fact that the physician's fee is really an honorarium, which is not supposed to represent the actual value of the services rendered, but is a sort of token by means of which the patient shows his gratitude. In earliest times such services were performed without recompense as natural acts of humanity. The first form of payment was a simple gift which in some instances consisted of munificent donations of land. Even at the present day in Russia physicians receive, instead of a definite payment for their services, gifts, whose magnitude varies according to the means or gratitude of the patient. The English consultant receives his fee wrapped in a bit of paper, as if it were a dishonor to see and handle the actual money. Payment in money has, however, been practised from the very beginning of recorded history, the Code of Hammurabi even mentioning such method of payment. With the growing complexities of modern life the various forms of medical service have been classified and given a "price" like so many commodities. Nevertheless, as Seneca says, "the physician is paid for his trouble; the patient remains indebted to him for his goodness of heart." If the doctor were paid in every instance for his actual labors he would be willing to forego the other form of indebtedness. At any rate the attitude of the public toward the physician's bill is frequently one of indifference, of grudging submission, or of hostility. This attitude has remained unchanged in spite of the fact that, so far as the body of the profession is concerned, the average fees have remained the same, while the prices of commodities have generally advanced considerably.

It is about time that the general practitioner should take a cue from his more prosperous colleagues in the specialties, namely, by demanding an adequate fee for work that is really of an expert nature. There need be no uniform office fee. With a stated sum as a minimum charge each patient should be taxed according to the nature of his ailment, and the degree of skill and the amount of time necessary in treating him. It is preposterous to assume that the same fee might be paid for treating a simple pharyngitis, as for making a thorough examination of the chest in a case of suspected tuberculosis. It will not take the public long to recognize the justice of this method of grading medical fees, which is in accord with strict and sane business methods.

The importance of exacting prompt payment is a fact that every practitioner learns after years of painful experience. Every language has a variation on the old rhyme, which Timothy Kendall in 1577 rendered as follows:

"Three faces the Phisition hathe:
first as an Angell he,
When he is saught; next when he helpes,
a God he semes to be.
And last of all, when he hath made
the sicke diseased well
And asks his guerdon, then he semes
An ongly Fiend of hell."

Prompt payment is the gist of the Latin proverb: "Accipe dum dolet, post morbum medicus olet." As the Germans say: "Lasst euch zehlen, wenn sie quelen." The French version is the following:

"Médecine et procure,
Fais-toi payer quand le mal dure."

According to the inimitable Scot:

"You shall take your fee whilst the tear is in the ee."

One cannot conclude this subject better than by quoting the section on compensation of the Principles of Medical Ethics of the American Medical Association: "It is unprofessional for a physician to dispose of his services under conditions that make it impossible to render adequate service to his patient or which interfere with reasonable competition among the physicians of a community. To do this is detrimental to the public and to the individual physician and lowers the dignity of the profession."

The Fee Book of an Irish Physician in the Seventeenth Century.—J. J. Walsh presents an interesting account of the fee book of Thomas Arthur, who practised medicine in Ireland in the early part of the seventeenth century. The first entries in the fee book are for the year 1619. Two pounds, equivalent in purchasing power to about fourteen pounds of modern money, was the fee, *collected in advance*, for the treatment of a case of simple gonorrhea. The list of patients and their ailments is interesting because of the terms used for the familiar diseases. There was one Anasthasia (*sic*) Ronan, a widow who was freed from orthopnea and paid six shillings eight pence therefor. Then there was one Gualterus (Walter) Meroney who *escaping* a putrid sore throat paid eight shillings. There is the story of a patient in detail with the account of the autopsy in order to show that the author was right and the other physicians in the case were wrong. According to this story, "Anna Gould in her fiftieth year of age and nineteenth of marriage to a second husband, though sterile, at length conceived and I told her from the evident signs of conception that she was pregnant. Some of my seniors in medicine, however, in whom she had greater faith than in me, treated her for ascites with hydragogue drugs and killed her in the eighth month of her pregnancy. At the autopsy which I succeeded in obtaining I took from her uterus a baby girl, dead but perfectly developed, and proved my diagnosis. For this I obtained not a little praise." Then he treats diarrhea and dysentery and a warm dyscrasia of the liver, and then another rather warm dyscrasia of the liver with hectic which had almost brought the patient into marasmus. There is an entry not so easy to understand with regard to a sufferer from blindness due to suffusion. Next comes a febrile sore throat, then a stomachic cardialgia which had been brought on by torrid bile. Then there was a palpitation of the heart and a woman freed from hysterical hydrops, and a stomachic cardialgia, then a cephalalgia. Then there was a young girl from the country whose name evidently he did not get, but whose fees amounted to one pound, who fell into a scirrhus of the liver from metastasis of her monthlies. Then there was an hysterical wife. Then the woman who had suffered from headache a few days before, came back with a slight fever. Then there was another case of fever and a boy freed from round worms. Then another stillbirth, and lientery, then ophthalmia, pleurisy, and then a girl with a boil on her arm which almost took away her life and only with the greatest difficulty was saved. Then there was a

sufferer from scotoma, one from elephantiasis, one from hypochondriacal melancholy, and next a fisherman caught by an anchor. In about ten months the doctor had made the equivalent of about $375 in our money, though in buying power this was probably the equivalent of some $2,000, perhaps more, in our time. In his second full year for which he gives thanks, he received 75 pounds, 18 shillings. One would expect somewhat more than this in his second year. In his third year, 1662, though he gives thanks to the Divine munificence as before for all His benefits, the sum amounted to only a little over 46 pounds. In 1623 it rose to 58 pounds; in 1624 it was 71 pounds; in 1625 it had reached over 86 pounds; in 1627 it was 105 pounds. This was the year after he had effected the cure of Archbishop Ussher. In 1628 the amount rose to 140 pounds. The following year it fell again to about 110 pounds and then below 90 pounds. In 1632 it rose to nearly 300 pounds, to sink again the following year to somewhat less than 250 pounds. His best years after this ran nearly up to 300 pounds and the average was about 250 pounds. For many years he must have made the equivalent of some $6,000 to $7,000 a year, comparing the buying power of money in both periods. Things medical were not nearly so different from what they are at present as one might readily presume them to have been nearly three centuries ago, and human nature was just the same. It is this that makes the dry bones of the old fee book live again and gives us a vivid picture of the physician who kept it.—*New York Medical Journal*, August 24, 1912.

An Antitoxin for Commercialism.—L. S. Pilcher alludes to the criticism recently made by a Frenchman, M. Menard, after a visit to America, that in this country, where money is the universal goal, medicine is not a liberal profession, but a trade. This criticism is too sweeping. The author admits, however, that in this country the absence of permanent class distinctions; the want of traditions strengthened by time and usage; the rapid development and extension of population and of large business interests, giving undue prominence to vigor in the affairs of life, and relegating to a minor place the things that make for grace and courtesy, art and refinement; the rawness and newness of much of our social state; the importance of immediate material success to be secured by the special activity of the individual; the small place for the hereditary influence of transmitted position and spirit—all tend to accentuate among us as a people the commercial spirit, the gospel of hustle and of material success. It is especially important that hereafter in the training of medical men emphasis should be placed on all those things that serve as an antidote to the commercializing tendency. The philosophy of medicine as illustrated in its history; the development of medicine as a part of exact knowledge, as illustrated in the successive phases of medical doctrine; the practice of medicine as seen in the various methods of different peoples and teachers; the medical spirit as typified in the lives of those eminent for merit and attainment in every age—should all form a part of the instruction given in an institution devoted to the liberal arts and sciences. The medical student in the early part of his course of training should be brought in contact with memorials of the careers and achievements of eminent medical men of all ages and countries. He should be made familiar with the literature of medicine. Systematic instruction in medical biography and in the history and literature of medicine should form a part of the teaching of the first years of the medical course.—*The Physician and Surgeon*, April, 1912.

The Increase of Malpractice Suits.—E. A. Sommer calls attention to the alarming increase in suits for alleged malpractice. The motive underlying many of these suits is the desire to escape payment of the bill for professional services. A large part of the litigation is caused by irresponsible attorneys. Formerly a certain class of lawyers lived by bringing damage actions against employers, but on account of laws that have been passed in various States, the amount of litigation along this line has decreased materially, and it has become necessary for such attorneys, in order to make a living, to transfer their attacks from the employer of labor to the doctor, the druggist, and the automobile owner. To illustrate the gravity of this situation in certain parts of the country, the following instance is cited: A busy country practitioner of Oregon, whenever he is called upon to reduce a fracture or perform any other kind of surgical work, exacts a release from the patient or the patient's nearest kin before he attempts to operate. In the State of Washington the situation with respect to damage suits has become so acute that a number of the physicians are forming private corporations, placing all of the stock, with the exception of two shares, in the hands of their families, the doctor retaining only one share, and all the doctor's property is conveyed to the corporation, so that if a judgment be obtained against the doctor, his private property and funds may be kept intact. It is suggested by the author that certain legislation may be of assistance in preventing the wholesale bringing of damage suits against physicians.—*Northwest Medicine*, August, 1912.

Sarcoma and Carcinoma.—In "Many Celebrities and a Few Others" William H. Rideing tells an amusing anecdote of James Payn, who, with his "Lost Sir Massingberd" and other novels, will be remembered as one of the "best sellers" of thirty years ago. At the time, Payn was editor of the *Cornhill Magazine*. One day an unannounced caller, who had managed to evade the porter downstairs, opened Payn's door. His hair was long, and his clothes were shabby and untidy. He had a roll of papers in his hand. Payn, surmising a poet and an epic several thousand miles long, looked up. "Well, sir?" "I've brought you something about sarcoma and carcinoma." "We are overcrowded with poetry—couldn't accept another line, not if it were by Milton." "Poetry!" the caller flashed. "Do you know anything about sarcoma and carcinoma?" "Italian lovers, aren't they?" said Payn, imperturbably. The caller retreated, with a withering glance at the editor. Under the same roof as the *Cornhill* was the office of a medical and surgical journal, and it was this that the caller had sought for the purpose of disposing of a treatise on those cancerous growths with the euphonious names which, with a layman's ignorance, Payn ascribed to characters in medieval romance.

To Avoid "Carbon" Trouble in the Automobile.—If a tablespoonful of kerosene is put into each cylinder immediately after a run, and allowed to stay overnight, all caking by carbon should be prevented. It is important to introduce the kerosene while the engine is hot, as the vapor which dissolves the carbon will not be formed otherwise. When next starting the engine, open the pet cocks in turn to aid in blowing out any solid particles.

SYPHILIS OF THE HEART AND BLOOD-VESSELS.*

BY GEO. RICHTER, M.D.,

ST. LOUIS.

PROFESSOR OF MEDICINE, AMERICAN MEDICAL COLLEGE, ST. LOUIS; MEMBER VISITING STAFF, ST. LOUIS CITY HOSPITAL.

THE localization of syphilitic disease about the heart and vessels is generally known; its clinical manifestations, however, are of the most complex and often confusing character. And even pathologico-anatomical findings are not well understood by many. Aneurysm and arteriosclerosis are frequently identified with lues, excepting, of course, senile changes and endocarditis from other causes, like rheumatism, gonorrhea, septicemia, etc.

It shall be my endeavor to point out the anatomical and the general clinical features presenting which may lead to some understanding as to how to arrive at a fairly correct diagnosis and to initiate a rational treatment.

It may be mentioned right here that the treatment in most cases cannot be simply a specific one, as we have to combat certain conditions which are not amenable to it, namely, secondary mechanical and other disturbances of the circulation.

The invasion of the spirochete and the flooding of the organism with its toxins set up certain well-known changes in the tissues. Their general character is an exudative inflammation with a predominance of changes in the blood-vessels, while a later, though at times still early appearing stage, exhibits the formation of the so-called gumma. The latter is as characteristic for syphilis as the tubercle for tuberculosis.

Syphilitic infiltration and gumna both undergo after a while regressive, degenerative changes, resulting either in destructive processes or in scars of great firmness and particularly prone to contractions of a characteristic, usually star-like shape. Such processes may be quite diffuse in character, appearing in interstitial tissues, accompanied or not by typical gummata, or localized and more or less clearly defined from neighboring tissues. The same is observed in hereditary syphilis, namely, diffuse or localized inflammatory processes involving largely the connective tissue.

Arteriosclerosis, on the other hand, is a condition distinct from lues. To understand this well we must recapitulate the normal structure of vessels, avoiding details. Capillaries consist of tubes of a single layer of endothelial cells. To them is added in the next larger vessels an adventitia or *tunica externa*, a membrane formed by fibrous connective tissue. Between the two appears the *tunica media* or muscularis, built from circular muscle fibers. The larger the artery the more pronounced will now appear a new layer between endothelium and tunica muscularis or media: consisting of connective tissue containing a great number of fine elastic fibers forming with the endothelium the *tunica interna*. The adventitia or external layer is connected with the surrounding tissues in a variable and often indistinct manner.

Of diseases of arteries there is recognized and of importance for our present consideration in the first place the endarteritis productiva, deformans, eventually obliterans. It consists in cellular growth of the intima. The intima becomes thickened, granulation tissue may develop. The vessel is apt to obliterate or thrombi form. Trauma and toxins are named among the causes, among the latter luetic toxins circulating in the blood and irritating the endothelium. It occurs also in the aorta as an immediate continuation of an endocarditis. In syphilis this condition seems to be quite rare, at least as an isolated process.

Another affection and one of vastly greater importance is mesarteritis productiva, or inflammation of the tunica media or muscularis: the ordinary form of specific syphilitic inflammation of vessels. Mesarteritis productiva syphilitica occurs in all vessels, but its seat of predilection is the aorta at or near the heart, in an average about one and a half inches above the semilunar valves, called "mesaortitis." The valves are usually not involved, but the coronary arteries frequently suffer from secondary conditions resulting from aortic changes, from retractions and partial occlusion, to which an obliterating arteritis of the coronary vessels may be added. Deep scars result, star-shaped with a thinned wall offering lessened resistance to blood-pressure and giving rise to aneurysm. Or, in other cases, flat plaques, slightly raised with fine folds covering the surface, or thick fibrous patches are seen. They may extend down to the thoracic aorta, often they remain isolated and small. They are quite characteristic, since the endothelium is not directly involved, occur with preference in younger persons, and cannot be mistaken for arteriosclerotic processes. The mesaortitis syphilitica may be further characterized by the presence of gummata. In purely syphilitic cases the intima is *never* implicated primarily in the process.

But, of course, there also occur cases where syphilitic mesaortitis is complicated by an arteriosclerosis, as in older persons. Then we find a thickening of the intima followed by degenerative processes, or also atheromatous degeneration.

Smaller arteries, most noted among them the arteries of the brain, exhibit two principal types of syphilitic disease, arteritis syphilitica and arteritis gummosa. There are also transition or mixed cases. In arteritis gummosa we find the disease attacking the adventitia and occasionally a secondary swell-

*Read at Symposium on Visceral Syphilis, St. Louis Medical Society, May 4, 1912.

ing of the intima frequently leading to obliteration of the vessel. The condition is comparatively rare. It may give rise to aneurysm of the arteries of the brain.

Endarteritis syphilitica shows a variety of forms, most notable being infiltrations and granulation-formations in the adventitia and perhaps a swelling of the intima leading to obliteration, while the media may remain intact (endarteritis luetica obliterans).

All these pathological changes are probably set up by the presence of spirochetes at the focus—they have been found there, but not in every instance. Either they have disappeared in the course of time or, as some believe, the condition is a metasyphilitic process, analogous to the changes in the spinal cord causing tabes.

If we compare with these arteritides the true arteriosclerosis we note that its most constant feature is a change in the *intima*.

Here appear first thickenings of the intima of considerable resistance which, as a rule, soon undergo repressive changes. The adjoining media may gradually participate in the process. Such regressive metamorphoses are most frequently met in the larger vessels, especially the aorta. Arteries of brain, myocardium, and kidneys have a tendency to undergo fibrous changes which are more diffuse, while in lues they are rather more circumscribed.

In arteriosclerosis of the aorta the intima during the first stage becomes thicker and then sclerotic, or it calcifies. Calcification is said not to occur in syphilis. In the second stage fatty degeneration sets in; partial necrosis, and the condition known as atheromatosis. Sclerosis and atheromatosis are two issues of the same cause: twins.* The latter, atheroma, leads more often to embolism, the former, sclerosis, to hypertrophy of the heart and high blood-pressure, but not necessarily to high arterial tension. Thus we may differentiate such cases clinically. The plaques are more pronounced where the blood-current normally meets pressure-changes, as the whole condition is ascribed to the results of continuous pressure-changes and pressure-increase, *e.g.* in men doing hard muscular labor. Such places are the openings of the intercostal vessels, the femoral arteries, also the radial and the temporal supplying the masticators. Under similar circumstances veins become sclerotic.

According to Kaufmann arteriosclerosis is in direct dependence upon the physiological gradual thickening of the intima in the growing organism, which continues up to about the thirtieth year. Then follows a standstill for about fifteen years. In the course of the following years normal elasticity becomes exhausted, connective tissue replaces the elastic fibers and protects the vessel against injury from steadily increasing blood-pressure. This compensation is, however, not lasting; fatty, hyaline degeneration sets in, resulting in so-called atheromatosis. According to this very plausible conception arteriosclerosis could not be called properly a disease; it is not due to an inflammation, but a very gradually appearing phenomenon of senility, apt to occur prematurely where organs have been abused or used up by unwise living. Parallel conditions are the failure of different glands to function well in the aging organism, like those of the digestive apparatus, internal secretions, and reproduction, the appearing of gray hair and of baldness. Such regressive changes are not diseases but may give rise to pathological conditions.

Arteriosclerosis of senility must, therefore, not be confounded with similar conditions of different etiological and anatomical character; for arterioscleroses due to toxins, to sepsis, to poisons are as a rule inflammatory processes which attack the tunica media and also the adventitia and only accidentally and at a later stage the intima.

We must distinguish between three separate conditions: (1) Senile arteriosclerosis, apt to appear before its legitimate time, as a condition of the aging intima; it may involve the media and occasion the formation of an aneurysm. (2) The infectious types attacking the media first, bacterial or toxic in origin; they also lead frequently to atheromatosis and aneurysm. (3) Lastly, syphilitic arteritis, in a class by itself, a disease of the media, extending to the adventitia and eventually, but not necessarily, implicating the intima.

Luetic arteritis is rather more frequent in younger years. Bittorf finds as average age of luetic arteriosclerosis about the forty-fifth year, while senile arteriosclerosis appears about the fifty-fifth year. Huchard collected 1,835 cases of arteriosclerosis and found as causes gout and rheumatism in 35.7 per cent., syphilis in 11.4 per cent., infectious diseases in 3.7 per cent. It attacks very frequently only a small surface of a vessel, it exhibits a tendency to obliterate the lumen causing fibrous changes, forms scars and partial retractions of the vessel wall, and shows no tendency towards atheromatous destruction or calcification so frequent in other conditions.

Aneurysms are commonly referred to arteriosclerosis in origin though they are in proportion to the frequency of arteriosclerosis as a subnormal condition really very rare and the fact that they occur so often before the "legitimate" age for arteriosclerosis, at least in many instances, tends to suggest that they may be due to several causes. Among them syphilis plays a prominent part. Krehl goes even so far as to say that aneurysm is rare without syphilis. At least about one-half of all the cases of aneurysm are due to syphilis. The proof for this assertion is found in that they exhibit mesarteritic changes, a diseased condition of the tunica media.

Syphilitic mesaortitis and syphilitic mesarteritis of the basilar and other vessels of the brain are not rare and often lead to aneurysms. The latter may persist for a surprisingly long time and not break

*G. Lemoine (*Le Nord Médical*, April 1, 1911) says: Lipoids, cholesterol, are built in the liver from fat, to an increased amount in infectious diseases. They are secreted with the bile, reabsorbed in the intestines and then circulate in the blood, largely impregnating the periphery of the leucocytes and aiding in phagocytosis. Toxins deposited on the arterial wall attract the lipoids (cholesterol) and biological combinations form between the foreign toxins and the organic antitoxins. The latter appearing in excess are liable to be deposited (by way of the vasa vasorum) in the arterial wall, giving rise to atheroma, a process analogous to the deposit of urates in gouty tophi and cartilages. (Calcification would then be due to the formation of insoluble calcium soaps from this greasy matter.) This explains the appearance of atheromatosis after infectious diseases. He adds that the blood of the tuberculous is very poor in cholesterol, hence a poor defense against the bacillus of Koch, while the gouty (and obese) possess an abundance of lipoids and "resist wonderfully against tuberculosis and other infectious diseases" (and therefore we feed the tuberculous with cod-liver oil?). Lemoine's theory is based on quantitative determinations of lipoids on and in the arterial wall in normal and diseased conditions and renders the appearance of atheromatosis (presenile) plausible as a condition different from physiological, senile arteriosclerosis. Both, of course, are liable to occur in the same individual.

at all; they may remain occult. The adventitia is strongly reinforced by dense connective tissue and withstands pressure quite effectually, as far as its own wall is concerned, while the pressure of the aneurysm on its surroundings is apt to destroy other tissues, even bones. Such aneurysms are probably oftener of syphilitic origin, for senile arteriosclerosis combined with aneurysm leads to an early decline.

Prompt recognition of the etiology has repeatedly resulted in a cure or marked alleviation of the condition.

Analogous are the findings in syphilis of the heart. Here also we must distinguish between senile arteriosclerosis affecting the intima—here called endocardium—and syphilitic myocarditis, corresponding to the gummous or diffuse infiltration of the tunica media—here the heart muscle itself—and finally the adventitia or the epicardium (pericardium). In other words, what has been said of endarteritis and of the mesarteritis applies also to the heart.

Senile sclerosis occurs on the endocardium and the valves with secondary regressive destructive changes.

Of much greater importance is of course the ordinary endocarditis of which a warty or verrucous and an ulcerating form are described. They are extremely frequent in inflammatory rheumatism and occur also after various infections of other character, like gonorrhea and sepsis. *But it must be noted that there is no true isolated endocarditis syphilitica,* neither a verrucous nor an ulcerating form. Destruction or impairment of the valves in syphilis is extremely rare and then due to primary affections of the myocardium continuing into the endocardium and involving the valves secondarily. Or also due to mesaortitis extending to the valves. Of greatest rarity is aortic stenosis in syphilis. Much more frequent is a regurgitation consequent upon a dilatation of the aortic ostium, after dilatation of the heart itself as produced by myocarditis syphilitica.

An isolated aortic regurgitation is almost always syphilitic. It is occasionally associated with tabes or progressive paresis.

Diffuse luetic myocarditis belongs to the rarities, as also gumma of the heart muscle. In some cases a gumma has involved the bundle of His, the Tawara node, or the venous sinus, each leading to impairment of conduction of the stimulus and consequent heart-block or Stokes-Adams syndrome, while myocarditis weakens the contractility.

On the epicardium we find gummata, diffuse inflammations due to them, and white patches. The latter are certainly not due to gumma or syphilis. The syphilitic epicardiac process is always continued from myocarditic disease. Aneurysm of the heart has also been observed in syphilis.

Now how do those anatomical changes induce constitutional or clinical symptoms?

We will have to consider primary and secondary effects. The invasion of the system by the spirochete is not to be discussed here, nor are the first changes occurring within the vascular system perceptible clinically. Great alterations may develop before the patient is aware of it. This is due to the wonderful adapting power of the heart and entire vasomotor system to changed, even to rapidly changing conditions. But almost suddenly this adaptability may fail and alarming symptoms spring up.

The clinical symptoms are caused principally by loss of elasticity of some part of the vascular apparatus, either focal or widespread. Thus originate aneurysms and arteriosclerosis. Or they may occur in consequence of arteritis obliterans, occlusion of an artery with consequent thrombosis, malnutrition, necrosis of corresponding tissues. Or a gumma may form a mechanical obstacle. Or, finally, retractions from scars left from destructive processes may interfere with normal functions. And, as it practically the case in all diseases, hampered functions awaken our attention.

The circulation of the blood is sustained not only by the rhythmical contractions of the heart, but just as well by the activity of the arterial mechanism. The arterial wall is composed of elastic fibers and of plain (smooth) fibers—muscles. These contract with each pulse beat, imperceptibly, yet with marked effect. They do not serve only to keep up a certain "tone"; for this the elastic fibers are responsible in the first place, to them the prevailing tension is due; they are the key in which the heart plays its tune. Changes in tension independent of pressure exercised by the heart take place almost constantly—variations of the heart's melody, and as a rule imperceptibly. These changes are regulated by the vasomotor centers and affect the various vascular territories differently within a given time. The blood supply to the individual organs changes according to their temporary needs. All this, as well as the dire results of any adverse interference which cannot be compensated is well known. It is not the heart which regulates circulation, but the entire vasomotor apparatus; and not only the centers either. It is true that the heart adapts itself to changed conditions, even during a single beat (Krehl), but its increased or diminished contraction and action can influence circulation only as a whole, not a single territory. Here the arteries of an organ come to play under the guidance of the respective centers. That the arteries should contract and expand rhythmically with each pulse beat in healthy conditions just so much that the passing of the pulse wave does not change its caliber would seem plausible when we observe the so-called capillary pulse (really a pulsation of the arterioles) in aortic regurgitation, when these contractions become visible. For such reasons Senac has called the arteries a peripheral heart ("les artères sont des vrais cœurs sous une autre form"). The relations between arterial tension and heart pressure are most manifold. Many ignore the fact that peripheral pressure, as measured on the radial artery, and pressure within the viscera rarely correspond. And, furthermore, arterial tension as felt with the examining finger, due to active contraction of the arterial wall over the flowing column of blood and clearly proven by the sphygmogram, may accompany high or low pressure due to the energy of the contracting heart muscle and vice versa. We meet high heart pressure (Fig. 1) with low arterial tension in many cases of aortic regurgitation, and low heart pressure (Fig. 2) with high arterial tension in some cases of aortic stenosis; low heart pressure (Fig. 3) with low arterial tension in typhoid fever and in abdominal diseases generally, and high heart pressure (Fig. 4) with high arterial tension are the rule in interstitial nephritis (with exceptions) —but in all cases subject to changes, for instance by action of drugs (Fig. 5), as well as they happen under physiological conditions. No one single

symptom, nor even two referring to one condition prove anything at all.

We are well aware of how complicated the machinery of circulation is and how seriously the slightest disturbance would affect the entire organism, if we were not so well provided with compensating arrangements, and also with a duplicity

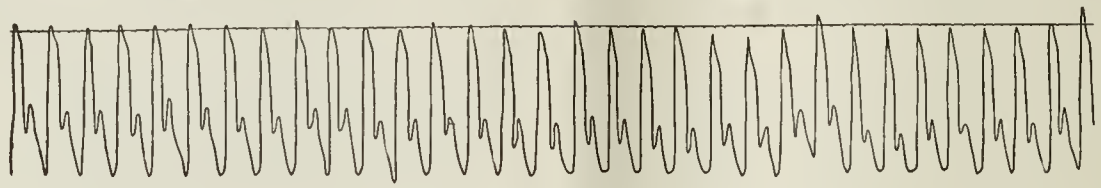

Fig. 1—T. L. M. Aortic regurgitation; syphilitic infection 30 years ago; healthy children; cirrhosis of liver; obese; no subjective heart symptoms; systolic pressure, 164 mm.; diastolic, 94; high pressure, low tension.

of most of the organs. Active automatism of the arteries is a postulate and enables persisting circulation even where the heart has grown extremely weak. Of this we make use in therapy, when we endeavor to attain comparative rest for the heart by increased flow of blood in the vessels of the periphery, not to have it stagnate there, but to circulate—by aid of the rhythmical contractions of the arteries.

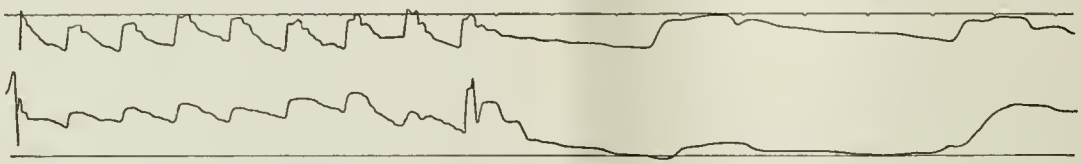

Fig. 2—J. C., 57 years old; arteriosclerosis and gout; slight anginal attacks; systolic, 120; diastolic, 70; low pressure, high tension.

In the aging arteries the elastic fibers disappear. Instead we find firm connective tissue with little elasticity; therefore, as a rule increased arterial tension. But also the muscle fibers vanish and the heart alone must propel the blood through the

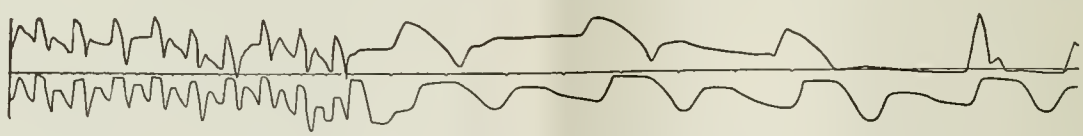

Fig. 3—Br. (colored), 23 years old; tuberculous peritonitis; upper curve carotid, lower radial; hypercrotism, as shown by carotid curve; systolic, 80; diastolic, 65; low pressure, low tension.

system. Therefore, increased heart pressure. The arteries have become incompetent, the work of the heart is increased. And as also a large number of the capillaries have become obliterated the heart would be unable to fulfill its task if the total amount of blood was not diminished. Hence again the lessened resistance of old people against many

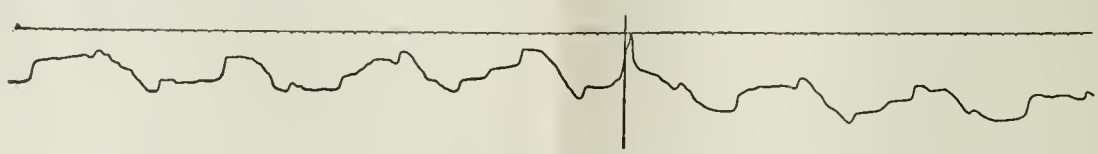

Fig. 4—H. K., 64 years old; luetic aortitis; severe anginal attack; pulse, grouping due to labored respiration; systolic pressure, 206; diastolic, 106; high pressure, high tension.

harmful influences, threatening a material shortening of life—but there has been a beneficent factor acquired, the immunity against many infections. Lessened activity, enforced wisdom, and close observation of individual experiences favor the arriving at even an extremely old age.

Atheromatous processes, the formation of aneurysms, alter this picture actually only in comparatively very rare cases.

Luetic arteriosclerosis shows a widely different aspect. Occlusion of peripheral vessels is caused in the senile form rather by thrombosis, in lues by an arteritis obliterans, in other cases again by a spastic condition localized in arteries of the extremities (as in Raynaud's disease and in many cases of diabetes); then one may observe sudden temporary limping, "claudicatio intermittens." Many draw a parallel between this and certain phenomena in heart action referred to temporary spasm of coronary vessels and of intestinal vessels, the so-called abdominal asthma. To the same class may belong the arteriosclerotic pancreatitis described by Opie, the acute fatty necrosis of the pancreas, certain cases of sclerosis of the liver, of contracted kidneys, of affections of the brain. They all are due to vasomotor disturbances, associated with some form of arteriosclerosis, and the younger the patients the more probably syphilis the cause, though other forms of toxemia must not be overlooked.

But the most dreaded of all such troubles is cardialgia, angina pectoris. As to its etiology Bouchard found lues the cause in 12 per cent. of all cases observed. Of 261 syphilitics 4.5 per cent. had angina, while of 3,739 non-syphilitics only 2 per cent. suffered from it. Angina pectoris appears in all gradations of severity, from an occasional vertigo or pain in the neck or shoulder easily mistaken for "rheumatism," with other symptoms, however, which clearly characterize the disease, to the most grave forms. The effect on the nervous system is so pronounced that the disease is comprised under the title of neurosis of the heart.

Many pathological conditions in the heart are apt to produce an attack; they all are based upon the physiological effect of heart failure. The following is the usual experience in arteriosclerosis:

The peripheral heart, the arteries have become incompetent. The central heart assumes their work, dilates, and hypertrophies. From overwork it becomes exhausted, it fails. It will fail so much easier and earlier, when itself pathologically altered, by arteriosclerosis. An attack of this kind will as a rule not be of extreme severity, for we have to

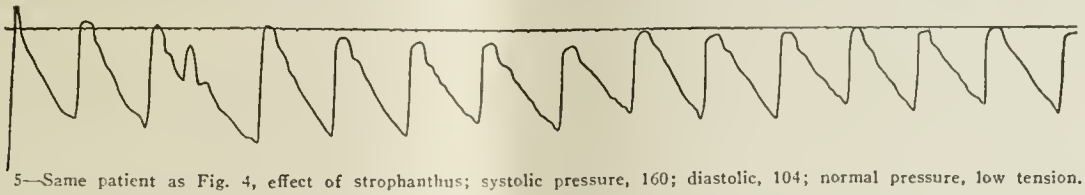

Fig. 5—Same patient as Fig. 4, effect of strophanthus; systolic pressure, 160; diastolic, 104; normal pressure, low tension.

deal here with conditions that supervene more gradually. Compensating factors are established and only extraordinary claims on the heart, *e.g.* by intercurrent disease, influenza very frequently, an acute indigestion coupled with an old albuminuria, are apt to bring on an attack.

In syphilis this process is ushered in in a different manner. Mesaortitis, and perhaps the not infrequent colonization of spirochetes around the aortic ostium, have altered the configuration of those parts. Or a myocarditis syphilitica has weakened the circular fibers around the aortic ostium; the semilunar valves have become insufficient. The arterial tree itself is but slightly affected. We diagnose a regurgitation with moderate systolic and abnormally low diastolic pressure. Of the condition of the arteries we learn by studying the sphygmogram. A pronounced dicrotic wave proves either lack of tension in the artery or a paresis of the arterial muscle fibers, while a descent somewhat delayed at the apex (a short plateau), yet very rapid, would indicate the presence of a certain arterial tension, and with the lack of a dicrotic wave perhaps means a delayed active response to the stimulus set by the pulse wave (Fig. 6). It would also point to a coexisting arteriosclerosis. These hypotheses might be substantiated by an electric arteriogram, supplementing the electrocardiogram. Still, the question of tension as against heart pressure can be decided only by the sphygmogram.

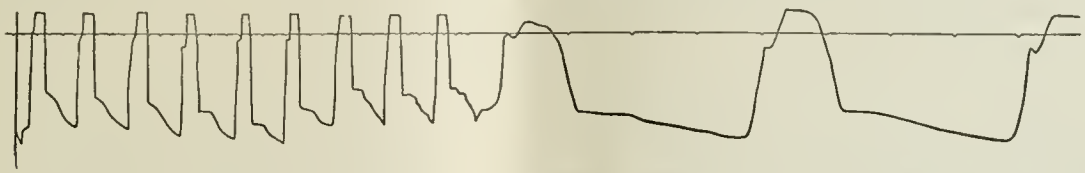

Fig. 6—J. I., 52 years old; luetic aortitis, regurgitation; no subjective heart symptoms; pain in neck and shoulder at night; infection 32 years ago; healthy progeny; disease remained occult until now (positive Wassermann); systolic pressure, 132; diastolic, 40; normal pressure, low tension.

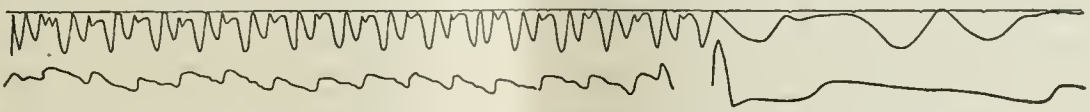

Fig. 7—M. (colored); luetic myocarditis; cardiac dyspnea and greatest prostration; upper curve taken in the fourth interspace on the parasternal line; lower curve, radial artery; systolic pressure, 170; diastolic, 138; high pressure, high tension.

While the arteriosclerotic may have many premonitions of his circulatory condition, it is usually different from the luetic. He is perhaps not aware of anything being wrong. He uses and abuses his system in his accustomed way and will not mind an occasional palpitation or fluttering of the heart. But quite suddenly, for some not always explicable reason, the heart "breaks down." It has used up all its reserve capital and fails—a sudden pang, a sensation of missed beats, perpetual irregularity of the pulse, a violent pain in the region of the heart, perhaps extending down the inner side of the left arm (Mackenzie), a sinking sensation, an unaccountable terror, syncope, Cheyne-Stokes respiration, Adams-Stokes syndrome, cold sweat; blood-pressure rises, at least at first, rapidly, the patient gasps. his face becomes livid or pale, profuse perspiration sets in. All or many of these symptoms produce a picture of suffering than which there seems none more heart-rending. Gradually the attack subsides, the sufferer feels most welcome relief. Such spells are brought on either by an unusual exercise, an exposure to cold, a psychic adventure—anything which causes contraction of a larger territory of capillaries and thereby suddenly increases heart action beyond its now inadequate adaptability and capacity for work.

Stealthily the incompetence of the heart becomes more permanent, lung congestion (weakness of the right ventricle) produces dyspnea, cardiac asthma; edema of the dependent parts is established, swelling of the liver embarrasses the abdomen, only a sitting posture allows a shadow of comfort—superfluous to dwell longer on this picture which we all have witnessed with anxious sympathy (Fig. 7).

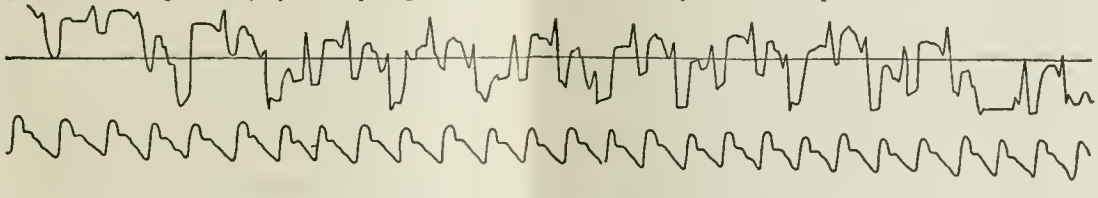

Fig. 8—Same as Fig. 7, compensation after 4 months' rest interrupted by many attacks; upper tracing jugular, lower radial; systolic, 144; diastolic, 80; normal pressure, normal tension.

It is particularly cardiosclerosis following myocarditis syphilitica which causes such havoc. In-

volvement of the organs of conduction of stimulus within the heart produces bradycardia, tachycardia, and frightens patient and attendants. Continuous irregularity of the pulse demoralizes circulation. The patient at last lies listlessly in his bed, or in a half-stupor, seems to be spellbound by the horrible stories which his heart whispers or hisses in his ears unceasingly. Motionless he lies unless a sudden attack of cardiac asthma arouses him from his lethargy to renewed and increased suffering. Daily we expect to hear of his demise—but he lingers on, he begins to breathe easier, his appetite returns, he ventures out of his bed. He recovers more strength and returns to a life of renewed activity (Fig. 8).

Are not such cases almost characteristic for lues: the sudden onset, the missing compensation, due to relative rapidity of the pathological process, the gradual reparation? The latter could not take place in arteriosclerosis, but occasionally in endocarditis.

The diagnosis of syphilis of the heart and blood vessels must be based on the same grounds which serve us in diagnosing other syphilitic manifestations. The syphilitic heart and blood vessels show clinically nothing absolutely characteristic, nothing which might not be found in other diseases. Our suspicion will be aroused when the patient is below the age of senile arteriosclerosis, when the involvement is essentially aortic and that an incompetency, when the symptoms supervene rather suddenly and are not accompanied by fever, thus excluding acute endocarditis from any other cause. The Wassermann and the luetin tests will show that syphilis is much oftener present in such diseases than has been surmised heretofore. It only remains to be stated that in such cases other evidences of syphilis, tertiary symptoms in general, are almost always absent, and that the first symptoms may occur as late as thirty or more years after infection and an uninterrupted general health.

But there are two other sides to the question after the presence of syphilis in the patient has been proven. Are the symptoms really due to syphilis or to other, complicating causes, like rheumatic endocarditis, or other toxemia, or premature arteriosclerosis? Here the art of the physician, not to say his instinct, may guide him better than laboratory methods.

And again, are the symptoms due to an active syphilis or are they the result of a previous and now terminated syphilitic process as encountered in tabes and in general paresis? Here a most careful analysis of all the symptoms may help us out of the darkness.

The prognosis is not absolutely bad; it depends of course upon the extent and the importance of the parts involved. A reparation is not rare, while it is impossible in senile arteriosclerosis.

As to treatment, nothing new can be advanced. Specific treatment is in most cases helpful. Why Ehrlich cautions against the administration of salvarsan is not quite clear. It has been given by many with excellent results. Digitalis and other bodies of the digitalis group often disappoint, though good preparations of strophanthus (however difficult to obtain) seem to be quite serviceable. Iodides seldom fail to benefit the patient, which may be partly due to their diminishing the viscosity of the blood and rendering the work of the heart so much easier. Intravenous medication (digalen, digipuratum, strophanthin-Böhringer) gives in appropriate cases decidedly better and often astounding results. Hypodermics of camphor, of caffeine, will tide over a dangerous phase. Nitrites in angina and hypodermics of adrenalin or of pituitrin are rapid in action and comparatively harmless, but the effect will not last and frequent repetition may be called for. The latter two are particularly helpful in cardiac asthma. Strychnine is of course a great stimulant, but has no direct effect upon the heart (Mackenzie).

In all other respects the management of such cases will have to be guided by the rather erratic rules governing treatment of vascular diseases in general. A close supervision of all the functions of the organism, careful regulation of the diet, a proper weighing of rest and exercise promise altogether better results than routine prescriptions and measures. Physical therapy is perhaps the most beneficial of all, but difficult to apply properly. Sweating and purging in edema exhaust the weak and hasten collapse—heart failure! A salt-free diet and restriction of liquids give more satisfaction (Karrel diet).

One must always keep in mind that the most desperate cases, that seemed absolutely hopeless, may recover.

3538 Humphrey Street.

CHLOROSIS AND TUBERCULOSIS.

By CHARLES M. MONTGOMERY, M.D.,

PHILADELPHIA, PA.

Chlorosis and tuberculosis are two diseases that have always been studied in conjunction by those who have felt any special interest in either one. In spite, however, of the numerous contributions to the literature in recent years little new light has been shed on any relationship that may exist between the two affections, and the most practical results that have been achieved have been to clear up certain misconceptions and to lay renewed emphasis on the importance of carefully investigating all cases of chloranemia for evidences of tuberculosis.

The present paper deals briefly with some of the questions arising from a study of chlorosis and tuberculosis, particularly in regard to the relationship supposed to exist between them, and presents for what they may be worth the data in any way bearing on the question of tuberculosis gleaned from forty-three case records of chlorosis obtained in the wards and the dispensary of the University Hospital. It was highly desirable to find out whether any of these patients developed tuberculosis later, but it was possible to get in communication with only seven of them after they had suspended treatment.

A description of the disease chlorosis will not be attempted here. Suffice it to say that the term chlorosis still stands for a fairly clearly defined symptom-complex, and that the chloranemia is simply one of the symptoms of the disease, and not necessarily the most important, some authors even asserting that the anemia is not absolutely essential to chlorosis. In passing, reference may be made to the well-known fact that the number of cases diagnosed as chlorosis is decreasing. This is to be explained at least in part by the relegation more and more of cases simulating chlorosis to the group of secondary anemias.

Etiology.—Chlorosis is rarely a fatal disease and little is known of its anatomical basis. Concerning tuberculosis as a factor in the pathological etiology, I can only say that I have been unable to find any

record of the presence of tuberculosis at an autopsy of a chlorotic patient. Our ignorance regarding the etiology of chlorosis is well expressed by R. C. Cabot (Osler's "Modern Medicine," IV, 642), who says that we know nothing about the causes of chlorosis beyond vague guesses suggested by certain statistics. A factor that has been frequently held responsible for some of the cases of chlorosis is tuberculosis. The imaginable explanations as to how tuberculosis produces chlorosis may be grouped under two general heads: (1) Tuberculosis directly by its toxic effects gives rise to the symptoms of chlorosis. (2) Tuberculosis indirectly by influencing the organism either before or after birth affects it in such a way that even after all toxic effects of the tuberculosis have passed off there remains in the individual an abnormal physiological or structural condition, the evidences of which are revealed by the characteristic symptoms of chlorosis. Thus in late congenital syphilis one sees symptoms resulting from toxic effects and structural change. It is part of the purpose of this paper to investigate how far the assumption that tuberculosis is a cause of chlorosis is justified.

Age.—Most of the cases of chlorosis occur before twenty-five. Cabot found 94 per cent. of 497 cases to occur between fifteen and thirty. All except four of the writer's forty-one cases with age recorded were under twenty-five years of age. It is strange if tuberculosis produces chlorosis that it does not do so more frequently at other age periods when tuberculosis is at least equally prevalent.

Sex.—If it is difficult to explain on the assumption of a tuberculous basis why chlorosis prevails chiefly in persons under twenty-five, it is even more difficult to explain why the disease is almost entirely limited to the female sex. The writer's forty-three cases of chlorosis followed the general rule that has few exceptions, all being in women.

Heredity.—Chlorosis often occurs in certain families, but is especially liable to be transmitted through the female members, therein differing from tuberculosis. A causal relationship between tuberculosis and chlorosis has been claimed by a number of writers because of the frequency of tuberculosis in the families of chlorotics. Van Noorden (Nothnagel, "Specielle Pathologie und Therapie," Vol. VIII, 1901, Die Bleichsucht) states that forty-four, or 20.3 per cent., of 217 chlorotics gave a family history of tuberculosis. In thirty-nine of the writer's cases five gave a history of tuberculosis in the immediate family, one other a similar history in a first cousin, and three gave a questionable history, while the remaining thirty-one furnished absolutely no family record of tuberculosis. But when one considers how prevalent tuberculosis is, even when there is no chlorosis, and how many deteriorating influences are at work in the class of families in which tuberculosis is most rife, he is left unconvinced by statistics as to any effect tuberculosis may exert through heredity in the production of chlorosis.

Occupation and Environment.—Finding chlorosis relatively often in those exposed to the same confining occupations and modes of life that are frequently encountered in consumptives, some writers have hastily concluded that therein lies evidence in favor of a tuberculous origin of chlorosis. One might equally reasonably attribute all other pathological conditions arising under like unhealthy influences to tuberculosis.

Blood.—The occurrence in chlorosis and tuberculosis of an anemia exhibiting certain similarities in both conditions has been a potent factor in forming the opinion that the two diseases are in some way related. Certainly it is a suitable question whether the chloranemia so often accompanying tuberculosis may not in some cases represent an early stage of chlorosis. Against such an hypothesis is the great frequency in acute and severe cases of chlorosis of a marked lowering of the hemoglobin percentage, while in tuberculosis (uncomplicated) the anemia is nearly always only slight in extent even in advanced cases. A few figures may be given to illustrate this point. Out of 352 cases of chlorosis R. C. Cabot (Osler's "Modern Medicine," IV, 647) found a hemoglobin percentage as high as 60 in only six and in none was it over 70. R. Stockman (*Edinburgh Medical Joural,* November, 1895) reported sixty-six cases of chlorosis, the hemoglobin varying between 20 and 66 per cent. The average hemoglobin estimate in Thayer's sixty-three cases was 42.3 per cent. In the writer's cases only two out of thirty-six had a hemoglobin estimates as high as 70 per cent., the highest being 73 per cent., while only five others reached as high as 60 per cent. In marked contrast are the figures for tuberculosis. Thus, L. Brown (Osler's "Modern Medicine," III, 256) gives the following hemoglobin averages in 154 cases: Male, incipient, 91.0 per cent.; advanced, 90.04 per cent. Females, incipient, 88.2 per cent.; advanced, 90.3 per cent. All of these cases had 75 per cent. hemoglobin or above except two, and none below 65 per cent.

At the Home for Consumptives at Chestnut Hill the following averages were obtained: Incipient cases, twenty-seven, average hemoglobin, 85.1 per cent.; moderately advanced cases, thirty-seven, average, 85.9 per cent.; far advanced cases, eighty-two, average, 82.6 per cent. These almost without exception had a hemoglobin percentage above 70. B. L. Wright and R. W. King (*American Journal of the Medical Sciences,* June, 1911) in a large number of cases of tuberculosis obtained an average hemoglobin percentage of 85. It is indeed hard to explain on the basis of any special relationship between tuberculosis and chlorosis why the marked cases of chlorosis do not oftener show evidences of tuberculosis, and why tuberculosis in all its stages usually presents a fairly high hemoglobin reading.

An investigation of the red cells and leucocytes does not throw any additional light on the relationship between chlorosis and tuberculosis. A relative lymphocytosis is frequently encountered in chlorosis and in early tuberculosis, but is a common occurrence in patients in a number of conditions in which there is blood of poor nutritive qualities (Cabot). Distinct differences in the two diseases are found in the total volume of the blood, this being increased in chlorosis through an increase in the amount of plasma, while the specific gravity of the plasma in chlorosis is diminished and in tuberculosis is normal or increased.

Symptomatology and Previous History.—The number of symptoms common to both chlorosis and tuberculosis might predispose one to think that some close relationship existed between these maladies. Thus weakness, dyspnea, palpitation, dyspepsia, menstrual irregularities, and even fever frequently accompany both diseases. But frequently a distinguishing feature is that a prominent symptom in one affection is insignificant in the other, and a relatively insignificant symptom in one

disease is prominent in the other. Certain localizing respiratory symptoms like cough and expectoration are usually early and prominent symptoms in tuberculosis and are frequently absent in chlorosis, while a normal weight often found even in severe chlorosis contrasts strikingly with the frequent loss of weight in tuberculosis. Dyspnea, a common symptom in chlorosis, is often quite marked entirely independent of the existence of cough, whereas it is rarely a prominent symptom in tuberculosis until cough and abnormal physical signs have developed. A symptom in chlorosis very suggestive of tuberculosis is the fever. It occurred as frequently as 361 times in 497 of R. C. Cabot's (Osler's "Modern Medicine," IV, 645) cases. It is usually slight in degree and irregular in course. "In the milder cases it rarely reaches above 100.5° F., and is present only a few days at a time, but in some of the severer types of the disease fever may be present constantly for weeks." In forty-two of the writer's cases eleven were free from a record as to any past or present condition suggestive of tuberculosis. The remainder revealed evidences that might be considered suggestive of tuberculosis. Cough, expectoration or colds were recorded in ten, blood-streaked sputum in two, chest pain in five, dyspnea in eight, palpitation in five, loss of weight in eight, and weakness in two. The temperature was recorded in twenty cases, being normal in five, between 90° and 100° in ten, and over 100° in five. The pulse rate in ten recorded cases ranged between 80 and 100.

Tuberculin Test.—The frequency of a positive tuberculin reaction has played its part in creating the impression that tuberculosis is responsible for some of the cases of chlorosis. Thus G. Zickgraf (*Fortschritte der Medizin,* Leipsic, XXVIII, No. 17, April 28, 1910) found a positive response in 74.8 per cent. of fifty-five cases of chlorosis in which there was nothing else to suggest the existence of tuberculosis. In forty-eight other cases the chlorosis accompanied manifest signs of tuberculosis. In the tuberculous cases in which the so-called chlorosis was the first or one of the first manifestations of the infection the patients reacted to the tuberculin test with a smaller dosage and in a larger percentage than the rest of the tuberculous suspects, and the percentage of negative responses was less. The reaction was obtained with five milligrams or less in all but five of the patients. These figures, impressive as they may seem at first sight, are not convincing in establishing a relationship between tuberculosis and chlorosis. In the first place, tuberculosis is an extremely prevalent disease as is proven by the tuberculin test and by autopsies. K. Franz's (*Wienek klinische Wochenshrift,* XXII, No. 28, July 15, 1909) well-known figures show a positive subcutaneous tuberculin reaction in 38.7 per cent. (Hungarians) and in from 61 to 76 per cent. (Bosnians) among 1,000 recruits. Naegeli found recognizable tuberculous lesions in 98 per cent. of 500 adults at autopsy. In the second place, Zickgraf evidently considered many mild grades of chloranemia, which were really tuberculous in origin, as cases of chlorosis. Out of three cases of chlorosis collected by the writer in which the tuberculin test was applied all gave negative results. In two cases the von Pirquet method and in one case both the skin and the eye tests were employed.

Physical Signs in the Chest.—Most writers have very little to say about the lungs in chlorosis, and references to any abnormal findings are very rare. R. C. Cabot (Osler's "Modern Medicine," IV, 645) says the respiratory system shows nothing remarkable except deficient expansion of the lungs. C. Luzet ("La Chlorose," Paris, 1892) states that the dyspnea of chlorosis is not accompanied by cough or any auscultatory phenomena capable of explaining it. He mentions a number of modifications in the respiratory sounds especially noticeable at the right apex, but not indicating the presence of tuberculosis. In thirty-three of the writer's cases the physical signs were recorded as normal in twenty-one, while in most of the remainder the descriptions referred to conditions at the right apex that could not be interpreted to signify either a normal or an abnormal condition.

X-Ray.—It is unfortunate that so few records of *x*-ray examinations of the chest are available. C. Von Noorden (*Medizinische Klinik,* Berlin, 1910, VI 1, p. 1) states that the *x*-ray reveals in chlorotics a high position of the diaphragm, but free pulmonary motion. He makes no mention of any evidences of tubercles in the lungs. A radiographic record was found in only one of the writer's cases, there being described a suspicious right apex and calcified bronchial glands. The von Pirquet test in this case was negative.

Evidences of Extrapulmonary Tuberculosis in Chlorosis.—Tuberculosis in parts of the body outside the lungs has been asserted to occur quite frequently in chlorosis. Von Noorden (Nothnagel, "Specielle Pathologie und Therapie," 1901, Vol. VIII, Die Bleichsucht) found a previous tuberculosis of the glands or joints in 17.8 per cent. of 217 cases of chlorosis. Among the writer's cases there was no record of any previous tuberculous condition. The glands were described in fourteen of the cases, in nine being normal. The descriptions in the remaining five cases were as follows: (1) palpable gland in right axilla; (2) enlarged cervical glands and small gland in each axilla; (3) few enlarged glands; (4) and (5) palpable cervical glands. In other words, there was no positive evidence of any glandular tuberculosis.

Ultimate Results in Chlorosis.—One of the most promising methods for investigating the relationship between tuberculosis and chlorosis is the following up of cases of chlorosis to see if they develop tuberculosis later. Hayem (quoted by C. Luzet, "La Chlorose," Paris, 1892) followed forty cases of chlorosis for many years and only two developed tuberculosis, both mild and chronic in type. A. Stengel ("The Diagnosis of Chlorosis and Chloranemia," *University Medical Magazine,* April, 1900) mentions two cases at first regarded as chlorosis soon after developing acute and progressive tuberculosis. The attempt was made to get in communication with all the cases mentioned by the writer, with successful results in only seven. The periods elapsing after the suspension of treatment varied between several months and several years. The patients were questioned as to their general health and strength, their weight, breathing, cough, expectoration, temperature, and other symptoms and illnesses since suspending treatment. Three of the patients had remained perfectly well. One complained of weakness, dyspnea, palpitation, and pallor, but was free from cough and expectoration. A second said she tired easily on walking. A third had some cough and expectoration, also an ovarian abscess, but the weight was normal. A fourth was feeling generally poorly, had a dry cough,

fever, loss of weight, headache, and nervousness. Of these four two were probably suffering from symptoms of chlorosis. In the other two it was impossible to come to any definite conclusion as to the existence of tuberculosis. In the only case in which a chest examination was obtainable the physical signs were normal.

Treatment with Iron in Chlorosis and Tuberculosis.—The value of iron in the treatment of chlorosis is referred to here merely in contrast to its value in tuberculosis. This difference is at times of aid in their differential diagnosis. In former times iron was considered as productive of hemorrhage and of rapidly fatal tuberculosis. To-day iron has its enthusiastic advocates in the treatment of tuberculosis, but it does not produce in this disease, especially in the absence of other treatment, the rapid and marked curative effects often observed in chlorosis. This difference in action of the drug towards the two diseases affords additional evidence that they are independent of each other.

This brief treatment of the subject, undeveloped, I regret to say, by much original evidence, may be concluded as follows:

While it may appear plausible at first sight to offer tuberculosis as a cause for chlorosis, such a relationship still lacks satisfactory proof. In a large number of cases of chlorosis tuberculosis can be reasonably excluded. Most of the cases that have been followed up in after years remain free from tuberculosis, but the available records of these cases are few. While the two diseases share common symptoms there is usually a marked difference in their relative intensity, and in many instances prominent symptoms of one affection are lacking in the other. Specially worthy of note is the common occurrence in chlorosis of a hemoglobin percentage below 70, while tuberculosis usually shows a percentage above this. Of distinct significance is the action of iron, which behaves as a specific in chlorosis, often producing, even in the absence of other treatment, rapid and marked curative effects, far more striking than the effects ordinarily following the use of the same drug in tuberculosis. Cases in which the chloranemia can be traced to tuberculosis should not be regarded as cases of chlorosis.

It is far from the writer's thought to minimize the importance of investigating all cases of chloranemia for evidences of tuberculosis. Such an investigation cannot be too thorough.

I wish to take this opportunity to thank Dr. Stengel and Dr. Klaer for the use of records at the University Hospital.

REMARKS UPON PSYCHOGENETIC CONVULSIONS AND GENUINE EPILEPSY.*

By L. PIERCE CLARK, M.D.,

NEW YORK.

In view of the fact that the more exact methods of psychonalysis have made closer and sharper the relationship between the psychoneuroses and the epilepsies, I trust such matter as may be brought out in this small paper will stimulate renewed study of the subject. Such study ought to further the ends of diagnosis, prognosis, and treatment of the convulsive disorders.

*Read before the third annual meeting of the American Psychopathological Association, Boston, May 29, 1912.

It is fairly well proven that so-called genuine epilepsy is a disease characterized by degenerative changes in the cerebral cortex of a widely variant character, but of sufficient histological moment to explain the type of disease. Inasmuch as the disease has a morbid anatomic pathology, it must be classed as an organic disease. In the light of these facts it is perplexing to note that convulsive phenomena of psychogenic origin, or from a purely nonstructural basis, should be confounded with the seizure phenomena of genuine epilepsy, yet nevertheless such continues to be the case. No doubt many atypical seizures seen in idiopathic epileptics, even though the comitial disorder is certain and positive, are often not really epileptic in character or origin. All such seizure episodes should be subjected to strict analysis. One often notes the disappearance of these atypical attacks in frank epileptics though the grand mal attacks themselves remain unmodified. I can recall five cases seen during the past year in which this outcome resulted. Indeed, a wise truism often applied in organic neurology, and attributed to Sir William Gowers, namely, that no two nervous disorders are mutually exclusive, is a good one to apply in these borderland nervous diseases. Without digressing too far from the logical development of our subject, one may say this principle has been brought out distinctly in psychotic disorders, where it has been shown recently that almost any psychotic syndrome, such as the manic depressive, the dementia præcox, etc., may be demonstrated even in such a well founded paradigm mental disorder as general paresis.

It cannot be successfully gainsaid that too little attention is still paid to descriptions of the various types of fits in genuine epilepsy. The rather superficial scientific attitude of assuming that one has sufficiently classified the seizure phenomena of a given case of epilepsy by designating the attacks grand mal, petit mal, and psychic, is an instance in point. I must say that after having dealt with the so-called idiopathic disease for years I am as keenly on the outlook as ever to find any classified case of the genuine disorder turn out to be an epileptiform expression of a more frankly and deeper seated organic disease or defect of the brain. Now that more team work is being done by the internist and the neurologist in our field, especially regarding metabolic defects, the keener must our apprehension be in this respect. What we may lose in directness and apparent grasp of the individual case is more than compensated for by a real insight into the particular morbid mechanism under study. It may be safely ventured, in view of the surprising gross defects at autopsy in brains of so-called idiopathic epileptics, that nowhere in clinical neurology are there greater results to be obtained for the advancement of neurologic science than in making carefully detailed descriptions of all types of seizures without employing fixed terms. When this plan is followed one is surprised to find not only episodes which are by no means really epileptic in character, but that even the classic attacks of the disorder are often widely variant. Evidently in different seizures of the one case many different cortical functions are participating at different times in the epileptic discharges. A pathological study of the variations of the different cortical areas involved in apparently identical epilepsies become more understandable when one takes our view of the clinical study. Following the above suggestions more carefully in future we may at least eliminate some of the

strangeness of this "strange disease." While the neurologist may have been concerned in the past with a more exact localization of the epileptic discharge, and would steadily reiterate the importance of a more exact study of fits, no less active and exacting have been the demands of the psychonalists who are contributing their share in this renaissance of the study of convulsive phenomena. They have found that many atypical epilepsies are really functional psychoses, and this is especially true of the psychic epilepsies. If one excludes the cases that show classic fits of epilepsy, at some time in their history, one might easily class the majority of the remainder as of psychogenic origin and therefore as really not epileptic at all. Even in those individuals frankly epileptic, their disorder undoubtedly predisposes them to a ready splitting of personality, not only expressed in psychogenic convulsions, but also to so-called epileptic twilight states, day dreams, temporary absences, frights, distractions, pure phantasies, and a notable criminal disposition due to suppression of moral inhibitory ideas. The post-epileptic automatism in its behavior, even when so prolonged and complex as to amount to a delirium or transient manic episode, is much better explained on a basis of a dream-state in which wish-fulfillment is the motive or ruling idea. This is commonly shown in institutional epileptics afflicted with nostalgia who show a tendency to wander away from institutions in which they are being cared for and the prompt cessation of such automatic tendencies when the same individuals are returned to their homes.

The admixture of psychogenic episodes in an otherwise classic epileptic is shown in one of my recent cases who has "ocular attacks" of blinding flashes of light, dizziness, faintness, and a sense of great dread and desire to escape from the house. The attacks occurred almost daily when she sat down to eat with her family. The understanding of these peculiar attacks was only partially cleared up in that this girl was one of the few survivors of the Slocum disaster. In further analysis it was disclosed that she has been separated for a long time from her German sweetheart in Europe whom she hears from infrequently and whom she wishes she might visit. Apparently the delightful picnic parties she and her family had with her lover's family starts day reveries at the meal time, and the Slocum disaster experience substitutes the peaceful desire to take the safe journey by ordinary transatlantic ship.

Such psychic episodes but a few years ago, and even in some quarters to-day, are called psychic equivalents, meaning in an ambiguous way that such phenomena replace and are a kind of mental epileptic fit. They are, however, but psychic episodes in an epileptic individual and may and do, as we all know, occur quite independently of epilepsy. Such individuals should not be declared epileptic upon such evidence alone though the state has many of the superficial resemblances of an epileptic attack. As Stekel, Jones, and others have shown, psychoneurotic individuals may not only have aura at these psychic episodes like genuine epileptics, but they may fall and injure themselves and, in exceptional instances, even have bladder incontinence, bite the tongue, and lose consciousness. There are no pathognomonic signs of epilepsy to-day. All have been overthrown. Medical literature is filled with instances where there is an over- or undervaluation of the individual symptoms according to the individual observer's viewpoint and the point he wishes to prove. The case is overstated when a hysteric or psychoneurotic episode would be classed as epileptic and understated in the reverse effort. However, the case which I had intended to report in detail cannot be charged to defect of the above view as the observations on the seizure attacks were made by the patient's relatives before any knowledge of the peculiar nature of the difficulty was thought of. The point I wish to make here is that in this case of psychoneurosis all the classic symptoms of the comitial disorder, that of epilepsy, were in evidence, even to that of tongue-biting and bladder incontinence. There were eight attacks of this character in this girl of twenty-five dating from August, 1904, to April, 1909. The diagnosis of epilepsy during the time of the attacks was entertained by at least three competent observers, and yet on mental analysis (not even yet complete, for the case history runs on like a Chinese drama) the attacks were all undoubtedly psychogenic in origin and not truly epileptic. The patient has been entirely free from any attacks or episodes whatever. No drug medication, of course, was used. This case showed none of the epileptic stigma in character, voice, disposition, intelligence, etc., and on the absence of these defects a diagnosis of the psychogenic nature of the different attacks was made and psychonalysis was undertaken. The case was easy of diagnosis compared with the one mentioned earlier in this paper, in which an association of the two disorders was in evidence. The lesson is plain, but a diagnosis of epilepsy without the mental stigma is impossible, especially when based upon any degree of combinations of symptoms of episodes or attacks themselves.

Psychoneurotic episodes are differentiated from epilepsy in that the former are disorders of association of ideas, have greater constancy, often prevented by hypnosis in suggestible individuals, and the same may be displaced or prevented by purely psychic treatment while in the majority of instances they are uninfluenced by sedatives. The amnesic episodes are purely functional in character as intelligence tests show none of the mental stigma of the genuine disease. Lastly, psychanalysis proves the psychogenic episodes are closely related to a wealth of pathogenic and dissociated and subconscious ideation. The treatment of these psychogenic attacks is by psychanalysis by the Freudian method. In my experience the completeness of cure of the psychic episodes is not so prompt or permanent in these association disorders as in the uncomplicated psychoneuroses. The sexual element in the defective ideation, too, is not so marked. It must be admitted in the majority of my cases that a bad heredity plays a very prominent rôle both for the epilepsy and its association disorder or psychic episodes. For the past two years I have attempted to do a psychanalysis on all my so-called genuine uncomplicated epilepsies with considerable success. It has proven of considerable advantage in these cases by clearing away some of the objectionable phases of the post-epileptic automatism. The treatment is an excellent accessory to the hygienic method, and appears to do good in somewhat the same way as it does in other weakened and unstable individuals and as a reinforcement of good moral characteristics as in the average person. However, a point of great value should be mentioned here that in the cured or arrested cases of genuine epilepsy the psychanalytic treatment has greatly helped in maintaining the proper standard of after living and care of the re-

covered state, a signal aid not otherwise possible.

It may be asked pertinently, how may one make a differential diagnosis between the psychogenetic convulsions and those of genuine epilepsy before the epilepsy has had time to develop the degenerative and mental stigma of the true disease? Such a question is robbed of its importance in greater part if one remembers that in beginning epilepsy with no accurately observed fits to assist one, we naturally turn to the analysis of the basic subsoil upon which this disorder almost invariably develops, namely, its heredity, the individual peculiarity of temperament, personality defect, the speech and conduct and defects in mental development. Too much in the past, both by relatives and physicians, has been charged to the mental deterioration of the disease itself, and too little to the constitutional inferiority type from which the disease springs. I venture to state that the peculiar constitutional defect of epileptics is usually in evidence in every genuine epileptic for years antedating the seizure history. From such a statement one may rightly infer that the opinion regarding diagnosis, prognosis, and treatment in any given case should be based upon the mental and physical make-up of the epileptics themselves, and not upon the character and frequency of fits. We cannot too thoroughly discourage the present tendency of considering the fit as the central figure of treatment in epilepsy, however apparently important, the psychic episode in the psychogenetic convulsions which resemble the epileptic fit may be and about which one naturally centers his attention in treating the latter affection. I believe the broadest biological conception of treating even the psychoneuroses will ultimately prevail over narrower views still sometimes taken.

84 East Fifty-sixth Street.

SOME REASONS WHY THE GENERAL PRACTITIONER DOES NOT MORE FREQUENTLY RECOGNIZE PULMONARY TUBERCULOSIS IN ITS INCIPIENCY.*

By GEORGE WILLIAM BEACH, M.D.,

SUPERINTENDENT, STATE SANATORIUM FOR CONSUMPTIVES, STATE SANATORIUM, CASS COUNTY, MINN.

There may be those who at the outset will ask, possibly with some indignation, that they be shown, first of all, that it is an established fact that physicians are remiss in diagnosing incipient disease. And no one can deny that at first thought it does seem unlikely that present day general practitioners should be delinquent in discovering the presence of a remarkably well-known disease, and especially one that is so frequently encountered by all of us.

To comply with this request, one could go back a good many years and, if need be, over a vast territory. However, it seems preferable to gather proofs from recent events in nearby territory, and I have, therefore, collected some pertinent data from the records of the State Sanatorium for the Treatment of Tuberculosis at Oakdale during the period extending from May 1, 1911, to April 30, 1912. These statistics concern Iowa patients sent to Oakdale for treatment by Iowa physicians. Let me say right here that we must not forget that no State demands a higher standard of medical education than Iowa, and that very many States require far less. So if I prove that my contention, *i.e.* that physicians are remiss in diagnosing incipient disease, is true for the State of Iowa, it may certainly be admitted that it is also true for other States, if not for other countries.

*Read before the Johnson County Medical Society, Iowa City, Iowa, June 5, 1912.

Let us then examine the records of this institution as they apply to the diagnosis of incipient disease made by physicians who saw the patients shortly prior to their admission. In the Oakdale Sanatorium the routine for admission includes the following: An applicant, among other requirements, must send a certificate signed by a physician of his locality, stating that he has tuberculosis and describing the extent of the pulmonary lesion. To describe this extent the physician is requested to use the well-known nomenclature of Incipient, Moderately Advanced, and Far Advanced, and while it is probable that, as a rule, the general practitioner has a fair idea of the definitions of these three terms, the following explanations are printed on the page opposite the one where he registers his opinion regarding the condition of the patient:

"Incipient (favorable): Slight initial lesion in the form of infiltration limited to the apex or a small part of one lobe. No tuberculous complications. Slight or no constitutional symptoms (particularly including gastric or intestinal disturbance or rapid loss of weight). Slight or no elevation of temperature or acceleration of pulse at any time during the twenty-four hours, especially after rest. Expectoration usually small in amount or absent. Tubercle bacilli may be present or absent.

"Moderately Advanced: No marked impairment of function either local or constitutional. Localized consolidation moderate in extent with little or no evidence of destruction of tissue. No disseminated fibroid deposits. No serious complications.

"Far Advanced: Marked impairment of function, local and constitutional. Localized consolidation intense. Or disseminated areas of softening. Or serious complications."

It is certainly necessary that there be precise definitions for such important terms and it would seem that there is very little in the above that might be considered in any way arbitrary.

Of the 260 patients admitted to Oakdale between May 1, 1911, and April 30, 1912, there were 96 whose admission blanks had not been filled in as to the extent or gravity of the lesions. Of the remaining 164, 90 were diagnosed by the general practitioner as incipients. From the findings of examination on admission the sanatorium physicians classified these 90 cases as follows: Incipient, *i.e.* confirming the diagnosis of the general practitioner, 23 or 25.56 per cent.; moderately advanced, 46 or 51.11 per cent.; far advanced, 21 or 23.33 per cent.

Sixty-nine were diagnosed by the general practitioner as moderately advanced. From findings of examination on admission, the sanatorium physician classified these 69 cases as follows:

Incipient, 2 or 2.90 per cent.; moderately advanced, *i.e.* confirming the diagnosis of the general practitioner, 32 or 46.38 per cent.; far advanced, 35 or 50.72 per cent.

Five were diagnosed by the general practitioner as far advanced. From findings of examination on admission the sanatorium physician classified these 5 cases as follows:

Incipient, 0; moderately advanced, 0; far advanced, *i.e.* confirming the diagnosis of the general practitioner, 5 or 100 per cent.

It is a dangerous matter to draw many conclu-

sions from statistics, especially when these latter relate to only one sanatorium and cover a comparatively short period, but from what I know of several institutions for the treatment of tuberculosis, I feel no hesitation in saying that experiences like those at Oakdale are not unusual, and that it is safe to say that the relative acquaintance of the general practitioner with the incipient, moderately advanced, and far advanced periods of tuberculosis may be more or less approximately expressed by the percentages of correct diagnoses as set forth in the above figures, viz., 25 for incipient, 45 for moderately advanced, and 100 for far advanced. In other words, he has much less knowledge of the signs of early disease than he has of those which might almost belong to post-mortem findings.

If, then, we have been able to demonstrate that it is at least not infrequent for the general practitioner to show a lack of acquaintance with incipient disease and confound far advanced cases with early ones, it also appears from our records that he has had ample time in many cases to reach a decision before he has finally diagnosed a most unfavorable period as an early one. One would almost like to think that such blanks were filled out by physicians who knew better, but whose overzealousness for their patient caused them to state the case mildly in the hope that the patient's application for admission would not be refused. But surely there are very few medical men who would put themselves on record as being guilty of gross inaccuracies in their diagnoses, and certainly it would be most uncomplimentary to the sanatorium physcians to take it for granted that they would not be sure to detect such obvious errors. Moreover, in not a few cases the physicians who reported moderately advanced and far advanced cases as incipient had treated their patients for months and even for years before making a diagnosis of tuberculosis.

Let it be well understood at the very outset that if it has been established that the general practitioner fails at times to diagnose early tuberculosis, it is neither in my intention nor would it be in my power to prove that he alone is to blame. It is the aim of this paper to place the blame for this delinquency where, in the writer's opinion, it seems to belong, and it will shortly be shown that this blame cannot by any means be placed at the door of the general practitioner alone. Of course, it is impossible for everyone to see such a condition in the same light, but if it is admitted that the diagnosis of early disease is not made as often as it should be, it is not surprising that there are many reasons for it.

The subject, in fact, is of vital interest to all. The general practitioner—hard working, underpaid, assailed by the interested sophistries of quacks and faddists, expected even by some of his most intelligent patients to know more than mortal man can aspire to, and distrusted by a few in every community as incapacitated by his very profession from knowing as much as an ordinary man—the general practitioner, I say, whose very generosity is misinterpreted and often turned against him, should wish to show himself capable of meeting a common problem—that of detecting a most frequent disease.

The patient, naturally, is the one who, in a way, is most vitally concerned, for it is often his life that is in the balance. If detected early, his disease has many times more chances of being permanently cured than it has when allowed to go unrecognized until moderately advanced or far advanced.

The non-tuberculous public has an interest equal, if not identical with, that of the patient, viz., that of being protected against the infection that is sure to follow in case the incipient of today is allowed to become the far advanced of tomorrow.

The teachers in our medical schools certainly desire to show themselves worthy of the confidence of the coming generation of physicians, who will make them arbiters of that important period of their lives in which they aspire to lay the foundations for an honest success, from a scientific and moral point of view at least. Finally, sanatorium physicians have helped more than is generally recognized to gather facts that have added to the sum total of our knowledge of this subject which we have seen to be of universal importance, and they are naturally interested in having patients sent them that have a reasonable chance of being benefited by institutional treatment.

At this point it will not be amiss to call attention to the fact that the responsibility of early diagnosis rests, in a large measure, and bids fair to always rest, with the general practitioner, inasmuch as those who specialize in tuberculosis are too few in number and too unevenly scattered throughout the country. Nor does the present warrant us in thinking that there will be any marked shifting of this responsibility in the future. Having endeavored to show that the general practitioner does not diagnosticate incipient tuberculosis promptly, we will first review the phases of the problem in which the blame may be justly attributed to him, passing on to the shortcomings of the general public and those of our medical schools. Lastly, we will consider the part played by the sanatorium physician.

The Faults That Lie with the General Practitioner.—He often fails to consider the possibility of incipient disease when confronted with such signs as slight loss of weight or strength which cannot be attributed to another cause, a persistent even if slight cough, slow recovery from influenza, change of character as manifested most frequently by irritability or indifference to matters that were previously of great interest to the patient.

He often fails to consider the probability, not to say the quasicertitude, of tuberculosis when consulted for a pleurisy or an hemoptysis.

Occasionally he is grievously at fault in turning his back on the fact that the patient suspects tuberculosis and desires a thorough examination.

There seem to be a few general practitioners who have no conception of pulmonary tuberculosis that is not far advanced.

It is not uncommon for the general practitioner to fail to have his patient strip to the waist for a chest examination, or to take too little time for an examination that often requires much mental concentration, honest reflection, and the use of three special senses—sight, hearing, and touch.

He sometimes omits to demand a second or a third examination when the findings of the first leave him in uncertainty. In this case he may put himself on record as denying, in the face of ample proof to the contrary, the existence of a very frequent disease.

He sometimes attaches an unreasonable and absolutely unfounded faith to the negative findings of the bacteriologist. Such men are, we all trust, less common than a decade ago, but they are still to be found. When a man discredits the diagnosis of a confrère or disregards physical signs and clin-

ical symptoms, because of negative findings of a sputum examination—such a man (I weigh my words well) may have a legal right to practise medicine, but he shows himself ignorant of what competent teachers throughout the world have unanimously agreed upon.

There are a few who make a diagnosis of incipient disease and keep it to themselves, fearing to have it contradicted by another physician who knows less than they do. Counting on the possibility of such cases recovering spontaneously, and fearing, above all, that they will lose with the dear public who nearly always side with the man whose words dispel dread, such general practitioners choose to be opportunists, confident that, at the worst, they will be able to assert to sympathetic ears that the onset of the disease was at a date later than their reassuring words.

The Faults That Lie with the Public.—The patient often expects the physician to arrive at a decision after a single and sometimes necessarily incomplete examination. Such patients will always listen less attentively to the conscientious, scientific man who takes time to collect his evidence and to weigh it carefully before giving an opinion than they will listen to the man who boldly asserts with glib assurance what he knows the patient desires to hear. One of the most common characteristics of the quack is to find out what the patient hopes to hear and then to hand it out to him. There are many today who complain that physicians have been remiss in not warning their patients of incipient tuberculosis. Such persons should be told that the public is very apt to get what it asks for. When a physician has lost several influential patients because he has told them they were tuberculous, he must have great moral courage and some financial independence if he persists in telling his patients the truth.

Furthermore, the public often refuses to compensate adequately the man who makes careful examinations and who gives his opinion honestly and fearlessly. If the sums of money paid by those suffering from early tuberculosis for patent medicines, fads, and confidence schemes of all kinds could be handed over to the general practitioner and he could be given an opportunity to see the patients and examine them, with the assurance that they would respect his decisions, I, for one, am convinced that more early diagnoses would be made and a large number of cases hindered from becoming progressive. That day will come only when the great public changes its present attitude of credulity towards the organized graft of nostrum manufacturers and all kinds of healers and ceases to look upon the disinterested efforts of scientific men with scepticism and distrust. Perhaps the layman would not persist in this attitude if he would reflect that the advances made in public hygiene and general prophylaxis have nearly all been made by the members of a profession which had only to lose, from a financial point of view, by consequent improvements in living conditions. The curious fact remains to be accounted for why the medical profession does not possess that confidence of the public to which it is entitled and of which it has shown itself worthy in a thousand ways.

The Faults That Lie with Many of Our Medical Schools.—The men who direct the policies of our medical schools are in a position to understand the needs of the present time and even, to some extent, those of the near future, when it is a question of practical instruction on subjects that are year by year becoming more important. The day is near when a medical school not having a chair on tuberculosis will be considered behind the times, and it is unfortunate that this fact has not been recognized sooner by those who preside over such important destinies.

It may be contended by some that the subject of tuberculosis may be treated quite adequately by professors of general medicine, but the facts do not support this contention. Students are being graduated year after year who cannot diagnose incipient tuberculosis. What is equally unfortunate is that they are often not even taught where to turn if they wish to make up this deficiency. The truth is that the methods employed in detecting early disease and in caring for tuberculosis in its various stages positively require expert training. The professor of general medicine cannot give it. This subject has developed too rapidly for him to follow it without neglecting his already vast domain. The professor of surgery admits the need of a chair of genitourinary diseases, of orthopedic surgery, etc. The occupant of the chair on clinical medicine knows that there must be a department on cutaneous diseases and one that concentrates vast energies on syphilis. Yet he takes no steps for special instruction to be given in the disease that carries off approximately one-seventh of mankind. For this reason, no special efforts being made to attract clinical material, such as an out-consultation or dispensary for pulmonary diseases, the students are not furnished with the necessary patients to be examined and followed up. A few far advanced cases sometimes filter in but are regarded with fear by the students, nurses, and employees and are scarcely made welcome.

The efforts of the average faculty are at present wholly inadequate to teach the undergraduate what he needs to know, not only about early diagnostic methods, but about the up-to-date management of the disease in general. Tuberculosis is today a subject as vast in itself as medicine taken as a whole was formerly. To be a well-equipped physician, one must know, at the very start, how to recognize the most common and one of the most lethal diseases of the present day. I am convinced that this is often not the case at present, and in support of my contention refer again to the statistics of the State Sanatorium at Oakdale during the past twelve months.

The medical department of the Iowa State University has taken some steps to remedy this situation and is unusually fortunate in having a sanatorium in close proximity. Several other medical schools throughout this country have made some efforts along the same line but the sum total of such endeavors is far below what is needed.

Finally, we come to consider in what measure sanatorium physicians are responsible for the fact that incipient disease often passes unrecognized by the general practitioner. One reason is that they take it for granted that many physicians not only have but little practical knowledge of tuberculosis, but also that they will never try to obtain any. Another reason is that they have often blamed the general practitioner as alone responsible for this deficiency, overlooking the fact that he has often been handicapped from the start by insufficient training as an undergraduate, and forgetting that in spite of his good intentions, there is not much chance for him to improve himself in this department today

unless he gives up more time and money than the average man can afford.

In general, the sanatorium physician has been obliged to teach himself much that he has learned in his special work and perhaps he consequently takes it for granted that there is no more scientific way of imparting a knowledge of tuberculosis. As sanatorium physicians are necessarily isolated and widely scattered, in addition to being hard-working men, they have not done all that they might have accomplished in devising and advocating means for giving students a better-balanced education and for giving physicians practical post-graduate courses. Lectures on tuberculosis, whether intended for undergraduates or for general practitioners, should not be given by theorists, but by men of practical experience, who are able to set forth lucidly and fully what combinations of signs and symptoms they depend upon most for diagnosing early tuberculosis and how best these signs and symptoms may be discovered. When the day comes that this special knowledge can be imparted systematically, both student and general practitioner will show themselves eager to avail themselves of it.

Having briefly enumerated the shortcomings of the general practitioner, the public, the medical schools, and the sanatorium physician and suggested remedies where they were not too obvious, but one thing remains to be done, viz., to consider the outlook and to conjecture what changes are likely—whether, for example, sanatorium physicians will endeavor to have chairs created whose occupants will teach adequately what is incompletely taught at present about tuberculosis, whether faculties will act upon such suggestions, whether the general practitioner will become more adept in handling tuberculosis, and, finally, whether the public will stop listening to frauds and lend an ear to the teachings of science.

As I see it tonight, the future is both hopeful and gloomy. It is hopeful in that the general practitioner is already manifesting in many ways a desire to perfect himself in early diagnosis. He has improved in this respect during the past five years and we have reason to believe that he will continue in his efforts to surmount, as in the past, one difficulty after another. It seems more than probable that the sanatorium physician may be counted upon to do his part and assist, as much as his busy life will allow, in the attainment of what is so vital to the interests of all.

It may be that the medical schools will move a little more slowly than we would like, but they too will rise above the influence of tradition and conservatism, even as they have done in the past. Some of them have begun to recognize the importance of a more practical study of tuberculosis and their progress may be more rapid than anyone can foresee.

But the layman—what of him? Can we count upon his cooperation in coming early for an examination, in accepting a diagnosis that it is painful for him to hear? It is from this point of view that the future seems most sombre. It is not because the layman is incorrigible, or incapable of learning better, or is not alert to the importance of the tuberculosis problem, but because of conditions that he cannot control. The immediate future offers but little hope of amelioration, for there is one cause that militates especially against the early diagnosis of this disease. I have kept it for the last, partly because it is the chief cause, and partly because it is the least amenable to medical science and to physicians as such. This cause for the frequency with which an early diagnosis is not made would remain if every sanatorium physician divided his time between his present institutional work and teaching methods for the early recognition and management of the disease. It would stay with us, obstinate and immovable, if every general practitioner should become an expert in tuberculosis. It would practically be uninfluenced if there were ten times the number of state sanatoria and if every county and large municipality were provided with a hospital for this disease alone and even if all beds were free.

The economic conditions in which a large proportion of our population live are such that even a short illness entails hardship and that an incapacity for work that runs into months spells despair. In dispensary work one frequently sees victims of far advanced disease consult a physician for the first time. They admit that they have had a troublesome cough for months or even years and that they have been getting weaker for a long time. But they have been working steadily on and proudly tell you that this is their first half-day off to see a doctor. If pressed with questions they will often admit that they have tried different patent medicines, upon which the physician with more or less tact blames them for their stupidity in not coming at once to a dispensary, whence they might have been sent to a sanatorium. The patient listens, sometimes respectfully, sometimes sullenly, but in his heart of hearts he feels confident even then that he was right in trying the patent medicine. It is true that the latter did not cure him, or even do him any good, but maybe (he argues) that was only his bad luck. On the other hand their advertising matter promised to cure him without loss of work, and the physician admits that he could not have done this. In other words, we find that sanatorium treatment or the rest cure at home are to many patients ghastly absurdities when it is considered that they could not afford to make use of them, even if they were free. For usually there are little children, the aged, or other victims of the disease, who depend upon the patient's earning power from day to day. Slowly he feels the grip of his foe tightening upon him. Yet a martyr to cruel social conditions, he works on and on until his hands lose their cunning, until his emaciated limbs refuse to carry him any longer to his work and until at last his mind is mercifully blunted by despair.

It is the experience in the Iowa institution, as in most others of similar character, that many patients leave against advice, long before they should, and return to the labor and the living conditions that were the causes of their original downfall. Some go away silent, others explain that their families have used up their small savings and are in need of the patient's wages, and nearly always the foreseen happens and the disease progresses with renewed activity. The public know our remedies: Sanatorium treatment and rest cure at home or in day-camps, and the public know also what we act as if we did not know, viz., that a large percentage of our fellows are as unable to follow the treatment that we prescribe as they would be if we ordered them to engage first-cabin passage to Europe and to take a three months' cure at Baden-Baden or at Aix-les-Bains.

This is the gloomy side of the question, because we see no means at present that can bring about any marked amelioration. Will the remedy come in the

form of a more equitable remuneration for the producers of our wealth? Or will it be through the creation of a government insurance against illness and accident, such as is proving successful today in Germany? It is impossible to say at the present time, but the question cannot fail to be of deep interest to the physician who longs to allay injustice and to relieve suffering that he is unable to reach at the present time.

CRITICISM OF ORTHODOX INTERPRETATIONS OF OCCUPATIONAL CRAMP-NEUROSIS AND THE TERM NEUROSIS.*

By TOM A. WILLIAMS, M.B., C.M. (Edin.).

WASHINGTON, D. C.

FORMERLY CORRESPONDING MEMBER PARIS SOCIETIES OF NEUROLOGY AND OF PSYCHOLOGY, ETC.; NEUROLOGIST TO EPIPHANY DISPENSARY.

Occupation cramp has been explained as a fatigue —"neurosis" of muscles, of nerves, and finally of centers. But as it is not repaired by rest, how can this be? Besides, the same act can be done with other implements, *e.g.* cases in which the individual can write with pencil and not with ink. It is far-fetched to suppose that "neurosis" can shift from one to another group of muscles or their centers. The term "neurosis" often explains nothing but the interpreter's ignorance of the process at work. Besides, "neurosis" does not last for years without further impairment shown by additional symptoms; while psychosis, that is ideational and emotional habitus, lasts a lifetime unless modified by therapeutic stimuli from without or within.

Therefore, occupational dyskinesia is purely psychogenetic, *i.e.* produced by an idea or its attendant emotion. A good example is the case of a telegrapher whose "hand-cramp" which had begun to show itself on raising his cup occurred only when he thought of it, and whose telegrapher's cramp began because of fear of losing his position as a stock broker's operator. Physical symptoms are not the cause of cramp in themselves, but may furnish the initial motive from which comes the notion of incapacity or of perverted movements. Such physical disabilities are frequently perpetuated into psychical ones, *e.g.*

An Incapacitating Hysteria Engrafted Upon a Hematomyelia of the Right Hand and Arm Segments.—A man of 20, apprentice mechanist since the age of 16, was seen with Drs. Conklin and Lewis Taylor in June, 1911. Two years before he had dived to the bottom of a creek. The concussion which ensued kept him in bed with severe headache and unable to move for three days. Urinary incontinence lasted one day. He vomited at first. For nearly a year he was unable to walk without severe staggering and his speech had been very difficult and still remained slow. He complained also of great sleepiness and difficulty in holding his water; so that he was quite unable to go to work, more especially as the right hand was partly wasted and paralyzed, and he feared that what he knew to be an organic nervous disease might be aggravated by exertion. There was loss of sexual power. The boy was normal with the exception of the following abnormalities: Reflexes—The right plantar was absent, but there was inversion of the foot on stroking the sole. The right triceps was diminished. Motility.—There was weakness of the extensors of the third, fourth, and fifth digits of the right hand to an extreme degree. The opposition of the thumb was not quite weak. The grasp of the hand and flexion of the wrist were relatively stronger. The abduction of the wrist was strong; the abduction of the fingers was quite weak. There was no other distinguishable weakness of the forearm. Sensibility.—He complained of a perpetual tingling down the right leg, which occurred with each beat of the heart, night and day, except during sleep. But there was no difference on the two sides in the perception of coolness and warmth; and the sense of attitudes was now normal, although he stated that for two months he was unable to recognize the position of his limbs. But I could not satisfy myself that he really felt less intensely, as he alleged, on the right leg when stimulated by the tuning fork and the point of a pin; so that this hypoesthesia might have been suggested during my examination. A suspicion of its psychogenic nature was corroborated when I found that although he declared he would sway when he closed his eyes, he did not actually do so when his balance was deprived of the assistance of his vision while I pretended to be examining the eyes. Diagnosis and Prognosis.—The abnormalities of the reflexes, motility and subjective sensibility, as well as the slow speech and difficult retention are due to organic changes, very probably hematomyelic, resulting from the blow on the head in diving. They are not amenable to treatment; but they are by no means incapacitating, for even the grasp of the right hand was fair and the right thumb could be opposed so that he could handle a tool. The prognosis as to efficiency was therefore good. Treatment.—Accordingly he was explained the organic nature of part of his difficulty; he was also told that the disease was not progressive, and would not be exaggerated by work, which would, on the

*This is not the place to discuss the significance of the term neurosis as contrasted with the term psychosis. It is unfortunate that most medical writers use the former term in speaking of the latter condition, as well as when talking of neurosis in the true sense, that is to say, an abnormal functioning of a neuronal system not arising from ascertainable structural defect. A disorder of a neuronal system is manifested by symptoms arranged topographically and applying to all the reactions dependent upon the neuronal system which is diseased. When a disorder extends only to particular acts, while other acts performed by the same neurones possess normal integrity, it is a misnomer to apply to it the term neurosis; for the disharmony occurs only in virtue of a perversion of the reactions of a system of governing neurones at a higher level, which are combined not in topographical symptoms, but by a functional interplay exceedingly labile in nature and dependent upon extraneous stimuli which can alter the order, extent, and intensity of the respective reactions innumerably, while the neurones in themselves remain perfectly healthy and susceptible of the reactions we call normal, provided that the order of their discharge can be regulated by teleologically appropriate stimuli. To such types of reaction we give the name psychic; and these, expressed in psychological terms, have nothing to do with those applicable to the reactions of healthy nerve as studied in the physiological laboratory, or of diseased nerve, as studied at the bedside. An example will make this clear. A wink may be a simple reflex, a purely neuronal phenomenon, the disorder of which may be termed a neurosis. It may, on the other hand, be the response to the complicated series of stored stimuli known as memories set into action by stimuli known as sensations and perceptions, and demanding for their orderly expression not merely one locality of the cerebrum, but the whole expanse of the cortex, both of the great and little brain. The function of teleological adaptation which eventuates in this second type of wink, we call psychological; and the disorder of such a function is named psychosis, the term neurosis being entirely inapplicable. (It is unfortunate that psychiatrists have confined the word psychosis to what they are pleased to call the true mental alienation, but this is no reason for perpetuating a usage of so confusing a nature.)

contrary, improve him in every way, and very likely rid him of his heavy feelings. I recommended him therefore to begin work and behave as if he were quite well. This he did with the result that he continued at work, and is in excellent condition at the time of writing, six months later.

No commentary should be needed to show that this boy's idleness proceeded not from actual disability, but from the ideas which he and his people held regarding his condition. He was the victim of a false fixed idea that he was gravely ill, and this suggestion was the cause of his incapacity when I saw him, while the organic destruction of the central nervous system had at that time no direct significance in that respect.

Case II.—Hysterical Habit Spasm After Appendicitis.—A single woman of 26 years was seen in 1911 with Dr. I. S. Stone. She had had a dull pain since an attack of appendicitis six years before, but had gone on working in her dairy in spite of it until it wore her out. After this a spasm of the iliac muscles supervened. She declared herself "nervous because I suffered so intensely." She would start at noises, and could not sleep after excitement, so that she gave up visiting her friends. The only neurological signs were the hyperesthesia and spasmodicity in the right iliac region. Treatment.—I taught her to inhibit the spasm by drill, and assured her that the hyperesthesia would disappear as a result of the operation which Dr. Stone had performed three weeks before. But as the spasm had become a habit, and gave rise to pain by stretching the muscles, she would have to learn to control it by means of a series of exercises in muscular inhibition which I showed her how to perform. She made quick progress at first, but relapsed on account of a physical depression, which I found to be due to disordered metabolism from the egg and milk diet which her recumbent position did not enable her to metabolize. When this was removed psychomotor discipline was again persevered with, and she returned home almost well two weeks after I first saw her.

These examples of hysteria, the suggestion for which arose from an antecedent physical condition, are paralleled in a comprehensible and simple fashion in the traumatized person whose back or shoulder does not recover from a blow, perhaps quite insignificant except in the patient's mind.* Still more simple is the example of the petulant child or woman who nurses and magnifies a trifling hurt into a serious injury because of a morbid way of regarding her privileges. All these symptoms have been perpetuated by a false notion concerning their origin. Even when a local or general physical state is recovered from, as by rest or metabolic regulation and good nutrition, cramp or a professional disability persists. This fact is too well known to need insistence. Therefore the physical state is not the cause of the cramp. Its genesis must be searched for in a psychological mechanism. I believe that cases I have reported† clearly demonstrate such psychogenesis. The therapeutic test is a further proof.

Physical treatment does not cure the cramp; but it makes easier the patient's effort, by putting him into the most favorable state of physical vigor for the mental exertion needed in giving the close attention required to wean himself from a bad habit and reeducate his special psychomotor activities into a good habit. That is, a sequence of energetic discharges of a psychomotor area which have by association acquired an order not desirable, is changed by intelligent practice into a sequence which conforms to the order desired. Coordination is then substituted for what is incoordinate as far as practical accomplishment is concerned. It is the reacquisition of an impaired or lost efficiency, not due to a fault of the machine, but to an error in the order in which its parts are put in action. It is the directing force which needs to be scientifically applied, and not the physical mechanism which requires repair.

The treatment based upon these principles is one of psychomotor discipline attendant upon the accurate ascertaining of the mechanism of the dyskinesia, always essentially psychogenetic. The technique is described in the current number of the *Journal of Abnormal Psychology* (Boston); also in the monograph in which the cases are described.

EXPERIMENTAL STUDIES OF THE ACTION OF ELECTRICAL CAUTERIZATION ON NEOPLASMS.*

By J. BENTLEY SQUIER, M.D.

NEW YORK.

PROFESSOR OF GENITOURINARY SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Indications for the use and the therapeutic value of the Oudin high frequency current, in the treatment of benign papillomata of the bladder have been established.

The studies which form the basis of this communication have to deal with the action of the Oudin or monopolar, and the d'Arsonval or bipolar current upon malignant growths of the bladder and otherwise. The work was undertaken in consequence of an unusual experience, where the use of the d'Arsonval current caused the disappearance of an extensive vesical carcinoma. The details of which are as follows:

A gentleman fifty years of age consulted me on February 4, 1912. One year previously, while in good health, frequency of urination had developed. Shortly afterwards blood appeared in the urine, associated with dysuria. The hematuria, intermittent at first, became continuous. In December, 1911, he placed himself under the care of an able urologist who cystoscoped the patient and discovered a large tumor occupying the right side of the bladder. This surgeon suspected malignancy, but decided to apply cystoscopic fulguration, if only to check the profuse hematuria. A number of attempts were made, but the excessive bleeding so interfered with the proper application of the treatment that it was discontinued.

It was shortly after this that the patient came under my care. He had now become greatly debilitated from the continuous loss of blood. He was voiding urine the color of mahogany and operation was decided upon, if only to stop the

*Read at the Twenty-sixth Annual Meeting of the American Association of Genito-Urinary Surgeons, Philadelphia, June 8, 1912.

bleeding from the bladder. To digress a moment, some time before in conversation with Dr. J. F. McCarthy, instructor in my department at the New York Post-Graduate Medical School, he had suggested the use of the d'Arsonval or bipolar electrical spark as a means for checking hemorrhage in such a case, and the possibility of obtaining a more deep-seated action upon the tumor than with the Oudin spark.

It appeared that here was a justifiable opportunity to put the suggestion to the test. On February 6, under ether anesthesia, the bladder was opened suprapubically. The fundus was found to be widely involved by a growth as was also the trigone in the region of the ureteral openings. The growth seemed limited to the mucous membrane in the fundal involvement, while in the trigone the deeper structures were invaded. The prostate was not involved.

The mass of tumor occupying the trigone was shelled out and the more superficial growth of the fundus curetted down to the bladder muscle. The bipolar spark was then applied to the interior of the bladder wherever any growth had been.

The technique of its administration consisted in placing the patient in a high Trendelenburg position, exposing the interior of the bladder by wide retractors, and illuminating it with a tantalum lamp. One electrode, a large flat plate, was placed beneath the buttocks and the spark was produced by inserting the other electrode, a cystoscopic fulguration wire, into the bladder through the suprapubic opening.

All hemorrhage at once ceased upon application of the spark. The bladder and suprapubic wounds were closed around tubular drains. Considering the condition of the patient before operation, it was remarked how well he had stood the operation.

Histological Examination of the Tumor.—Microscopic examination shows two types of carcinoma—one in which there are small aveoli of carcinoma cells, and the other, the predominating type, in which there are papillary tufts clothed with a mass of cells of cylindrical and flattened variety. Diagnosis: Papillary carcinoma.

The post-operative period developed many interesting features. Six hours after operation, the drainage tubes becoming occluded, the patient passed urine by urethra absolutely free from blood. This was the first time for over six months that hematuria had been absent. Convalescence progressed favorably and at the end of five weeks the abdominal wounds were healed. He was passing urine free from blood and there had been no return of the hematuria since operation. Seven weeks after operation sudden death occurred from pulmonary embolism.

The bladder was removed after death and sent to the pathologist for serial section and minute study. There was no microscopical evidence of carcinoma either in fundus or trigone.

Histological reports on the removed bladder are here given in full: Specimen: Bladder. Examination reported March 25, 1912. Microscopic examination: Certain portions of the bladder wall show total absence of mucous membrane, the submucous coat being very rich in vessels, and being diffusely inflamed. Evidently there has been some post-mortem degeneration, for the tissue takes the stain poorly.

Other sections show inflammatory involvement of fat and of the serous coat; total absence of the mucosa, the submucosa being necrotic. Still other sections which are better preserved also are devoid of mucous membrane, there being a very vascular submucosa with evidence of chronic inflammation. A portion of the bladder wall, in all probability taken from the region of the sphincter or of the prostatic urethra, shows intense postmortem desquamation of cells, marked atheroma, calcification, and endarteritis of some of the larger vessels. There are islands of cells of probably desquamated epithelium (not neoplastic). No definite evidence of carcinoma.

Examination reported, March 27, 1912. Further study of sections from bladder show marked necrosis of the inner vesical layers. Inflammation without any trace of carcinoma.

Examination reported, April 1, 1912. Further material from bladder specimen: Microscopic examination of the wall of the bladder shows extensive necrosis of the submucous layers, absence of the mucous and marked inflammation of the submucous coat. There is no vestige or the slightest evidence of the presence of carcinoma.

A few days before operating upon the patient whose history has just been related, I had opened a patient's bladder for carcinoma, instituting suprapubic drainage, but making no effort to remove the tumor.

Believing that I now had at least a sure means of controlling hemorrhage, I offered to make an attempt to remove the tumor, to which the patient acquiesced. This patient was sixty-five years of age, the hematuria, although having been present for eight months, had not produced so grave an anemia as in the preceding case.

The second operation was performed on February 8 and a tumor about two by three inches in size excised. It was situated around the left ureteral opening extending up the fundus. The lower end of the ureter was firmly attached to the tumor and it was necessary to cut the ureter away from the tumor and transplant it.

The cavity remaining after excision of the tumor was thoroughly cauterized by the bipolar spark.

The patient recovered from operation without incident and the post-operative period was free from hematuria. Up to the time of his death, three months later when he succumbed to a rapid growing carcinosis, he had had no recurrence of hematuria. The recurrence of the carcinoma was in the intestines, omentum and liver.

This method of treatment has been employed in five other instances; a large papilloma was removed by suprapubic incision and the base sparked; two cases of prostatic carcinoma, in which the cavities made by removal of the prostates have been cauterized by sparking; two cases of vesical carcinoma have been sparked through suprapubic incision, without any attempt at excision.

These cases are too recent to draw any conclusions from, but will be reported in a further communication. In all these cases, however, one is impressed by the absence of any amount of bleeding after operation, and to the comparative small shock shown by the patient, even though they have been subjected to a very considerable period of anesthesia.

The experimental work on animals has been conducted at the laboratories of Dr. Francis Carter Wood, Director of the Crocker Cancer Research, who placed his facilities at my disposal.

The following is a brief abstract of some features of the investigation.

The experiments have been carried out on tumor bearing large white rats, and though the series is still incomplete the results are significant. The rats had been inoculated subcutaneously with either a carcinoma of high virulence or a sarcoma. Both of these tumors as a result of repeated transfers are now so virulent for rats that practically all inoculations are successful.

The first series consisted of five animals, of which two had sarcomatous tumors, one measuring 1.5, the other 3 cm. in diameter. The growth was in the subcutaneous tissue of the abdominal wall. The other three rats had carcinomatous tumors, two measuring 1 cm. each, and the third 1.5 cm. in diameter. These tumors were also loose in the subcutaneous tissue and could be freely moved about. The tumors were thoroughly fulgurated with bipolar electrodes, the distance between the poles being the diameter of the tumor. In two cases the current burned a hole in the skin and the tumor was loosened from the surrounding tissue and fell out. This material when examined microscopically did not show any evidence of extensive alteration; the staining qualities of the cells were merely somewhat less marked than in normal tissues. This shows that the cells were not much burned, but merely heated sufficiently to coagulate the proteid. All of this series of five animals died in from one to seven days. In all remnants of neoplasm could be found at the original site of the tumor. Death was not due to extension of the tumor; the lesion found was an acute enterocolitis resembling that found after severe and extensive burns. The only conclusions which can be drawn from these experiments, therefore, are:

1. That the current is not entirely a harmless agent.
2. That it does not actually char the tissues very extensively.
3. That it does not touch extensions outside the field of the main growth.

In the second series six animals inoculated with carcinoma were used. Two of the tumors were large and ulcerating, the other four were small, not over 0.5 cm. in diameter. Five of the rats were treated with fulguration; in one the bipolar current was used. This last animal died a few minutes after the cessation of the application of the current. Of the five remaining tumors four appeared to be actually growing, one appeared to be stationary. At the end of twelve days the infected surfaces of the two ulcerating tumors had become clean, healthy granulations, though the tumors are extending.

It is evident from these experiments that neither the direct treatment with bipolar current for fulguration or malignant new growths is capable of destroying all the carcinoma cells in a given area. While the use of the current is valuable in checking hemorrhage, as in bladder operations, it can by no means be assumed to replace extensive resection in the cure of carcinoma. Its action is probably simply that of an easily handled cautery.

Further experiments are being carried on, detailed statement of which will appear in a later communication.

49 East Forty-ninth Street.

Anaphylaxis in Burns.—A. Alhaique notes that animals that have recovered from a burn are more susceptible to the influence of a second burn, to which they may succumb, although if it had been the initial burn it would not have caused death. The serum of a guinea pig that has been burned when injected into another guinea pig imparts to the latter this hypersusceptibility to burns.—*Pathologica.*

TICS AND THEIR TREATMENT; EDUCATION VS. HYPNOSIS.*

By J. H. LEINER, M.D.,
NEW YORK.
ASSISTANT ADJUNCT NEUROLOGIST, BRONX HOSPITAL AND DISPENSARY; CLINICAL ASSISTANT, NEUROLOGICAL DEPARTMENT, GERMAN POLYKLINIK.

Tic involving a single muscle or a group of muscles is to be considered as a contraction or twitch, either arising in response to an external sensory irritation, or originating without the afferent impulse, when it is then purely a psychic condition, *i.e.* psychomotor. Charcot believed that it always was of psychic origin, but Brissaud first, and Miege later, after studying carefully these conditions, concluded that a good part of them were due to external irritation.

A further French classification divides these habit spasms into two main groups: (1) In which there is a simple spasmodic movement of different muscles particularly of the face and upper extremities. (2) In addition to the above muscular spasm there are explosive utterances and psychic symptoms. This variety, in my opinion, should not be placed under the classification of a habit spasm or habit chorea. Although they were named as impulsive tics of Gilles de la Tourette, nevertheless, if one observes a case of this kind he cannot help but consider these symptoms as belonging to hysterias, especially when the symptoms of mimicry, obsessions, and fixed ideas are very pronounced.

When these movements primarily originate as a result of some external irritation it becomes a tic only if there occurs a repetition of movements, first *involuntary*, which later fixes itself as a habit, the original causative factor often disappearing. The case I am presenting shows this phase very strikingly. As the patient goes along these coordinated movements grow more intense, more frequent, making the sufferer's lot miserable, and if an adult, often depriving him of his livelihood.

If its origin, on the other hand, is purely psychomotor, as a vast majority show this mode of onset, in the so-called imitation variety, it begins as a *voluntary* movement, the end result being the same as above mentioned. Whatever the causative factor, these co-ordinated muscular contractions become later entirely involuntary, convulsive in nature, and beyond conscious control.

Tics appear mostly between the ages of five and twelve, this being the impressionable period of childhood. Male and female are found equally affected. It may appear at puberty, and if in old age, it is either a symptom of senility or of Senile Dementia. In going into the history of these patients, neurotic antecedents can be most often ascertained. Often following an occasion of either anxiety or shock there is a gradual onset and development of these symptoms. The intensity of these contractions are, however, variable, so too, the duration of the invasional period. Spontaneous recoveries are recorded but are very rare indeed. The variety of muscular involvement, either singly or in groups, are as varied in this condition as there are human faces. Tic may affect any part of the voluntary system, showing a selective tendency for involving the muscles of the face, and diminish in frequency as we pass down the body. They may show wrinkling of the forehead which is a very common condition, jerking of the head, twitching or turning body, spasms involving the motor oculi,

*Read before the Northern Medical Society, June 28, 1912.

and often cases where the risorii are so markedly affected (as in this case) that they produce a picture reminding one of Hugo's "L'Homme Qui Rit."

This brings me to the treatment of these cases, as instituted in the neurological clinics in this country, and advocated in American text books of recent date.

Educational Treatment.—The essence of this treatment requires the patient to keep his mind on his spasm and try to control it voluntarily. He must go through daily exercises contracting the muscles involved in the twitch, and those that are the opponents. This task is impossible most of the time, and it is often necessary to get somebody who can control the patient, hold him well in hand, to have him undergo these daily exercises.

We find that this educational treatment is one of very long duration and ofttimes makes the condition worse in view of the patient's concentration upon his malady. This patient, whom you see, when he had his mind centered upon himself, became overwhelmingly worse. It is a prime requisite in instituting this class of treatment for children, that they should be completely isolated, taken from their parents, and unless the treatment is administered by a specially trained individual it will give poor results. Practically speaking, a great many patients suffering from tic come to clinics for treatment, and they are certainly, as you know, a very difficult lot to manage. So it is apparent that this method is not an ideal one by any means when dealing with practical conditions.

Hygienic and Medicinal Treatment.—This treatment is either given alone, or in combination with the above. Hygienic management is the *sine qua non* for all functional maladies that overtake childhood and although a great factor in treatment, is not the main therapeutic measure for the cure of this condition. Medicinal treatment by drugging the patient with arsenic should be absolutely avoided. I have in mind one case in particular where in addition to hygienic measures, arsenic and bromides were given for over a year and a half consistently, but with no results whatsoever.

Bearing in mind the inadequacy of therapeusis in such conditions this case may prove of interest because of its obstinacy and mode of treatment.

Patient A. R., male, 31 years old; born in Hungary; occupation, Bonaz embroidery worker. A neurotic family history was not elicited. *Personal history:* Does not smoke, drinks moderately of coffee and tea, does not partake of alcoholics. Venereal history denied. *Present history:* In the early part of December, 1911, patient began to have pain in both eyes, particularly in the left. This continued for several weeks when he was advised by friends to go to an optometrist to have glasses adjusted, who very readily advised him to do so. About this time he commenced to blink his eyes and roll them, imagining there was some foreign body therein. He next attended two eye clinics seeking for relief, but with no result. Finally he came to the German Polyklinik's Eye Department which he attended, and finding they could not do anything for him he was transferred to the Neurological Department. Here we instituted the classical treatment for tic, but with no avail. I took him in hand then after he had gone along for two and one-half months, beginning at first with a slight blinking of his eyelids, now, however, presenting a far different picture.

He showed a marked spasm of his forehead, involvement of the motor oculi, orbicularis palpebrarum, risorii, buccinator, orbicularis oris and other small muscles of the face. This combination of muscular movement when acting simultaneously was very bizarre. He wrinkled his forehead, rolled his eyeballs, beginning by looking inward toward his nose, then sweeping them upwards making a complete semicircle of 180° until he came to the outer canthus, then bringing them in again to the inner canthus; concomitant with these movements he used his risorii and other facial muscles and when one looked at him he gave the impression of laughter. This would keep up all day long, showing contractions at the rate of about forty times to the minute. He would, however, stop it while asleep at night, but the moment he awoke it began over again. Sometimes he would stop during the day but only for a few moments.

Treatment.—The first day I saw him, after ruling out organic disease, I tried hypnosis. He was put under the hypnoidal state—in this state of hypnosis, as you know, there is no amnesia—and I gave him suggestion for only a couple of minutes. When I awoke him all his symptoms had disappeared. He looked and felt just as he did twelve weeks before, when he had perfect control over his eyes and facial muscles. For ten days following he was entirely free from his condition, when he began to blink his eyes again, once or twice hourly. This was controlled. I put him under twice again because of his complaint that he had had two or three spasms daily. I finally thought that if I instilled into his subconsciousness a new complex which would act as an inhibitory factor it would entirely control his spasms. This method proved successful and it is now four months and not once has he shown any spasm whatsoever.

Although the educational method in the treatment of these conditions has shown a fair percentage of effective cures, nevertheless the inference I desire to draw from this obstinate case of tic is that if hypnosis were more often and widely used it would show, in my opinion, better results. The case before you could not possibly have been controlled by the classic treatment; however, it readily yielded to hypnosis.

421 Wendover Avenue.

A METHOD OF ANOCI-ASSOCIATION FOR ABDOMINAL OPERATIONS IN SELECTED CASES, WITH NERVE BLOCK À DISTANCE.

By LEIGH F. WATSON, M.D.,

OKLAHOMA CITY, OKLA.

Following the principles of anoci-association worked out by Crile, it is interesting to note the excellent results produced by a combination of local and general anesthesia for abdominal operations in selected cases. Several years ago Bodine advocated local anesthesia for appendicectomy, with a few whiffs of chloroform or nitrous-oxide gas for freeing and treating the appendix.

Crile and Bloodgood employ nitrous-oxide gas administered by a skilled anesthetist. In certain localities nitrous-oxide gas and an experienced anesthetist are not always obtainable.

With a proper selection of cases I believe there are less shock and postoperative pain when the operation is begun and finished under local anesthesia alone. Those who have had experience with local

anesthesia for abdominal incisions realize that an extensive and systematic infiltration of the different layers of the abdominal wall is essential for complete nerve blocking. It is seldom possible effectually to block the nerves of the fascia, muscles, and parietal peritoneum, especially in fleshy subjects, until the skin and fat have been incised, no matter how painstaking the infiltration.

With the patient under general anesthesia we have no means of knowing how thoroughly we have isolated the shock-producing impulses from the brain. The operator must be familiar with the technique of local anesthesia and able to gain and maintain the confidence of his patient, to use this method successfully.

Cocaine is best suited to this method because novocain is too slow in appearing and too fleeting in its effect completely to block the sensory nerve impulses during the ordinary operation and the closure of the wound. Braun and Lennander state that novocain is unsatisfactory unless combined with adrenalin to prolong its action, and even then the anesthesia is not complete for twenty to thirty minutes after the drug has been injected. With an incomplete nerve block, even though the patient is under general narcosis, there will be sensory nerve stimulation and exhaustion of the brain cells with its resulting shock.

Cocaine, 1 :1000, with adrenalin is as safe as novocain 1 :400 for the most handicapped patient. The cocaine anesthesia is complete within two minutes and lasts for three to four hours. When cocaine in physiological salt solution is used for the abdominal incision the tissues heal more promptly than after the use of quinine and urea.

For the prevention of postoperative pain in the wound for the first few days following operation, quinine and urea injections act admirably if made with a long needle into the tissues, at a distance (one to two inches) from the margin of the wound. As each layer is sutured the quinine and urea solution is injected, so as to block the nerves of this layer of tissues and yet not interfere with the healing of the wound. Postoperative anesthesia persists longer when the quinine and urea injection is used in this manner, for it is well known that a local anesthetic lasts longer in tissues that are not cut. After-pain in wounds is undoubtedly largely dependent on the degree of traumatism inflicted during operation on those structures possessing an abundant nerve supply.

Reclus and Lennander were among the first to note the comparative freedom from after-pain enjoyed by patients who had been operated on under cocaine anesthesia.

The quinine and urea nerve block *à distance* prevents postoperative stimulation of the brain cells, therefore there is no after-pain. When possible I believe it is always best to begin the operation with cocaine anesthesia and reserve the general anesthetic, even though it is nitrous oxide, until required for the intraabdominal manipulation. When nitrous oxide is not available and there is no contraindication, I prefer a few drops of chloroform when the intraabdominal manipulation requires a general anesthetic. With this method it is seldom that the patient need be completely under the anesthetic. Nausea and vomiting are absent, except when it is necessary to give ether, and then are slight because of the small amount required.

With this combined method the amount of the general anesthetic used is reduced to a minimum and the nerve block is more thorough than when the local anesthetic is hastily injected after the patient is under general narcosis.

I have used this method in performing a hysterectomy for a ten-pound fibroid of the uterus. The patient's pulse was 84 before operation and dropped to 72 before she left the operating table.

A patient with a very large ovarian cyst had a pulse of 80 throughout the operation. Unassisted she turned on her side after the cyst was incised, and when in bed after the operation remarked that she felt like taking a nap, she was so comfortable and free from pain. This patient did not receive a preliminary dose of morphine or hyoscine. In cocaine appendicectomies and exploratory laparotomies the pulse is rarely more rapid after than before operation.

This method requires more time than does the method of Crile and Bloodgood, because there is less general anesthesia used. It is impractical for large clinics, though for the majority of operators it has many advantages.

To appreciate the merits and gain the greatest proficiency in the technique of the combined method of anesthesia it must be used in every case no matter how small the operation.

In conclusion, with a sufficient dose of morphine or morphine and hyoscine to exclude worry, fear, and nervousness there will be no psychic shock. With a local anesthesia nerve block *à distance* sufficient completely to isolate the brain from the field of operation, there can be no exhaustion or shock of the subjective mind.

611-13 Colcord Building.

Rare Complications of Exostoses.—P. Sourdat notes among the complications of exostoses the following: pressure effects on the skin and nerves; painful contractions of overlying muscles; the development about the exostosis of a serous bursa which may become inflamed, and the detachment of a piece of cartilage from the surface of the exostosis, and its presence as a foreign body in the bursal sac. Of greater rarity is the ulceration of blood-vessels lying in proximity to the exostosis, or the traumatic fracture of the exostosis itself. The author reports a case of each of these accidents. One was that of ulceration of the peroneal artery by an exostosis of the tibia. The other was that of fracture of an exostosis of the lower end of the femur.—*Archives Provinciales de Chirurgie.*

The Treatment of Scarlet Fever with Moser's Serum.—B. Schick lays down the following principles that should govern this method of treatment: (1) The treatment should be applied only to those cases of doubtful prognosis and to those ordinarily fatal. (2) The injections should be made as early as possible, preferably during the first two days of the disease. The third day decides whether the treatment will be successful or not. After the fifth day of the disease the serum has no effect. (3) Cases most suitable for the treatment are those with toxic scarlet fever and those in which the throat complications are absent or are markedly developed. (4) Only those sera should be employed whose efficiency has been demonstrated. (5) The amount of serum to be injected is 200 c.c. In children up to one and a half years of age the amount should be 100 c.c. (6) All other therapeutic measures should not be omitted, especially all those that are designed to save the heart. Moser's serum is the only remedy of value in the toxic cases of scarlet fever. In these cases one should inject the serum not as a last resort but early in the course of the disease.—*Therapeutische Monatshefte.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, October 5, 1912.

THE ABUSES OF POPULAR MEDICAL EDUCATION.

ONE of the most powerful weapons in the campaign against disease is the enlightenment of the public in the principles of hygiene and sanitation. During the past few years medical men have been encouraged to assist in lifting the veil which hides the facts of disease from the eyes of the laity, and to accomplish this object through the medium of the lecture platform, the popular magazine, and the daily newspaper. The results have more than fulfilled the expectations of the most ardent advocates of popular medical education. Recently there has been a veritable inundation of newspaper and magazine articles on medical topics. Physicians have abundant opportunities for noting the avidity with which these articles are read and commented upon by the public. While not denying the possibilities for good associated with this method of aiding the cause of preventive medicine, it must be admitted that there are certain grave abuses that are at the same time bound up with this form of popular instruction. These abuses have not yet been sufficiently emphasized.

Conspicuous among the latter is the powerful influence exerted by self-appointed teachers who adopt the methods of the theatrical press-agent, but whose knowledge and experience are not sufficient to enable them to speak with the voice of authority. There is reason to suspect that some of these false prophets secure a self-exploitation that is not technically in violation of the code of medical ethics. The public should be warned particularly against those writers whose glittering and epigrammatic style enables them to give force to teachings that are founded neither on close observation nor on sound reflection.

There is a growing tendency to uncover some of the repulsive aspects of disease, to make direct and veiled appeals to the prurient, and to discuss in public subjects that should be reserved for the privacy of the home or the consulting room. Is it wise to break away from the reserve which has been one of the cherished ideals of the medical profession for many generations? The public is entitled to know everything that may in any manner assist in preventing or fighting disease. But this is no license for the dissemination of statements that are not the product of ripe reflection, for the exploitation of theories that have not yet received the sanction of the medical faculty, and for the circulation of doctrines that run counter to the seasoned opinions of the entire profession. The public press with rare exceptions has failed to exercise a wise censorship of medical news, and only too frequently has opened its columns to the half-baked hypotheses of sensational and pseudo-scientific medicine.

A CITY'S WASTE.

THE health conditions of any community are largely affected by the manner in which the waste is disposed of. Whatever else is done, this waste must, first of all, be rendered innocuous to the citizen. It is a fundamental duty of boards of health to formulate and to get inexorably enforced adequate regulations concerning material of which an American city of half a million gathers annually some 300,000 tons—fermenting, decomposing, putrescent, malodorous matter, food for rats, and other disease-conveying scavengers, breeding places for flies and other infection-spreading insects. Franz Schneider relates in the *Scientific American* of July 13, 1912, how New York and other cities cope with this problem. The annual refuse of the metropolis (not including its sewage or other liquid, but only the dry or relatively dry part of the city's waste) equals in volume ninety *Titanics*, and at least three great pyramids of Ghizeh. Evidently the problem of how to dispose of such masses is one of the first magnitude, requiring the greatest engineering skill and the expenditure of large sums of money.

In rural districts waste disposal is a comparatively simple matter: garbage is fed to the stock or ploughed into the ground; old paper and other combustible material are readily burned, and unburnable material goes into an innocuous dump heap. In cities the problem is much weightier, and is made more complex by the diversity of urban industries. For purposes of discussion four general classes of refuse may be recognized: garbage, ashes, rubbish, and street sweepings. Special waste from slaughter houses and putrescent animals from the public streets will be encountered, but the main phases of the problem are as here indicated.

In any comprehensive plan cognizance must be taken of the methods of collection. In some communities the householder must put his garbage and rubbish in separate receptacles, and these are separately carted away. In England, on the other hand, garbage and refuse are treated together, so that there is no occasion for separating them. The means of collection and disposal are at present almost as varied as the character of the material itself; yet here is one of the factors which must be settled in any scheme. Garbage is sometimes merely dumped on land—a procedure unesthetic and absolutely repugnant to sanitary science; or it is dumped in water, a serious nuisance resulting from material drifting back on the shores. The only methods really deserving consideration are reduction and incineration. In the former it is aimed to recover the grease from the material. Two to three per cent. of the garbage is thus extracted as grease, fertilizer stock which is sold to farmers

being the residue. Reduction is usually attended by unquestionably objectionable odors, wherefore plants to this end must be located far from cities, the expense of haulage being thus also an item. However this method may pay private concerns, it is questionable if it pays cities. The reduction method is distinctly American, and is little practised abroad where incineration is preferred. Garbage disposal by this method must be considered with relation to other classes of refuse; the heat for incineration must be obtained not only from the garbage itself, but also from other combustible waste. This method is most sanitary, giving, besides, clinkers which are valuable in construction work and for filling, paving, and concreting, while the resultant may be transformed into steam or electrical power. The problem of collection is also thus simplified, and as no odors come from the "destructors," they are placed in the municipal interiors, by which arrangement the haul is shortened and the cost diminished. In the earlier attempts at incineration the furnace temperatures at natural draft were too low, so that objectionable smoke and noxious odors resulted. But with the introduction of forced draft at 1,250° F. such difficulties have disappeared; and in Europe, especially in England, incineration (not cremation, which requires the expense of coal or other fuel not derived from the waste material) is "complete, unobjectionable, sanitary, and sometimes profitable." We have not space to consider further the disposal of ashes and rubbish, except to note that the picking over of rubbish is a very dusty and assuredly unhealthful occupation. Street sweepings with manure are placed in the ground, or dumped, or, best of all, incinerated.

The actual detailed plan which would be most efficient for any given community can be determined only after an investigation of its refuse, of the character of the community itself, and of its environs. A method must be selected which will remove the wastes quickly and completely from sight without nuisance or danger to health, which will recover whatever is valuable, and which will be carried on in every phase at the minimum expense.

INHERITANCE OF DISEASE.

Our medical forefathers believed in the inheritance of disease, at any rate, to a very large extent. Gradually belief in the influence of heredity has waned, until recently the pendulum has swung almost completely in the other direction and it is almost heresy to assert that any disease can be inherited directly. The researches and teachings of Weismann have had much to do with the change of front and other biologists have carried his views to the extreme. Karl Pearson has been perhaps the most conspicuous protagonist of the doctrine that acquired conditions are not inherited, and that no matter how greatly the body is abused the germ cells are unaffected. Readers of the Medical Record may recall the statistics compiled by Pearson, some two years ago, showing that the children of alcoholics received no injury from the habits of their parents. This statement was apparently riddled by Sir Victor Horsley, and a heated discussion took place between the two eminent men, resulting, in the opinion of most authorities perhaps, in overthrowing Pearson's assertion.

At the meeting of the Canadian Medical Association held recently in Edmonton another doughty champion of moderate views as to the inheritance of disease discussed the matter. J. George Adami in the course of an able address said that he was sufficiently old fashioned to repudiate the new-fangled "Weismannism" and still retained the belief that the sins so-called of the parents against the body, or at least a very important series of such sins, do influence the progeny unfavorably. And what is more, he believed that these new ideas had their origin in the narrowness or, if the term might be used, Chauvinistic provincialism of the zoologists. He pointed out that the vitality of the offspring was gravely affected, and from observation of families of alcoholics observed by him he could not but feel that children of confirmed drunkards showed an increased susceptibility to the action of relatively small amounts of alcohol. As for infectious diseases, he said that time and again the practitioner had observed a relationship between chronic or acute infection suffered by either parent and abortion, blighted ovum, stillbirth, or monstrosity. Time and again also the ordinary practitioner had been convinced that the children of those suffering from tuberculosis and syphilis were not merely of lowered vitality or more liable to succumb to childish ailments, but notably, in the case of tuberculosis, exhibited a peculiar liability to succumb to the same parental disease. Attention was drawn also to the fact that inheritance of disease is far from being everything. From the point of view of eugenics, there were to be considered the terrible effects of congenital diseases, more particularly of infections conveyed to the growing individual while in the womb or during parturition. Of course, the results of gonorrhea and syphilis from this standpoint are manifest to every physician, and the ills that follow in the wake of venereal diseases are now becoming obvious to the layman. The speaker urged that one should no longer approach the subject with false modesty and self-consciousness but should grapple the question boldly, and with ripe knowledge of the origin of the scourges measures could be put into force which would eradicate the evil.

However, the most interesting part of the addresses was that which dealt with inheritance of disease, and it is refreshing in these days to meet one bold enough to promulgate opinions in opposition to those of possibly the majority of authorities. There are signs that the extreme views held with regard to the non-inheritance of disease are beginning to be regarded with a certain amount of distrust and the address of Adami will tend to hearten the doubters.

GERMS AND TUMOR CELLS WHICH "DIE ON THE PREMISES."

Those who seek to rid their domiciles of rodents know how often one nuisance is replaced by another through the death of the animals in their haunts. It may seem a crude and farfetched anal-

ogy between rats in the household and animal and vegetable parasites of human beings or between the former and irresponsibly proliferating tumor cells; yet at present the pathologists are being confronted with much the same sort of a problem as the aforesaid vermin-infested householder. Once they succeed in destroying the activities of bacteria and tumor cells, the very death of these individuals forms a new source of danger.

We have learned in late years that certain substances are by selective chemotherapeutic affinity enabled to cause the death of tumor cells; but through the fact that these structures so destroyed must undergo chemical decomposition with the formation of absorbable toxic products these discoveries are largely invalidated. We have also learned that it may not be an unmixed blessing to destroy in an instant all the pathogenic bacteria in the body, for the numerous untoward results from salvarsan appear to be due in part to the absorption *en masse* of the decomposition products of the destroyed spirochetes.

The success of antidiphtheritic serum in neutralizing the toxemia of the disease, while at the same time the local proliferation of the bacteria was inhibited, has led us, perhaps, to expect too much from this plan of therapy. In a current number of the *Berliner klinische Wochenschrift* Geronne announces that while he succeeded in overcoming the blood infection in croupous pneumonia through early intravenous injection of a new serum, the local condition, so far from showing a parallel improvement, yielded in certain cases the very opposite results. The lungs did not clear up as they ordinarily do, and in two instances the patients had rusty expectoration for days. These results appear to show that in filling one indication satisfactorily we may set new irresponsible mechanisms in motion. The antipneumococcus serum in neutralizing a toxic principle in the blood may have paralyzed the phagocytes or autolytic euzymes or whatever principle it is which presides over the rapid absorption of exudates. We must hark back to the old dictum of *primum non nocere*.

Non-Material Cure of Common Warts.

The statement often made that removal by any material method of warts upon one hand may result in spontaneous disappearance of the warts on the opposite hand may be received in various ways. We may answer that such cures have never been subjected to rigorous analysis, or that they have resulted from mere coincidence or from mental impression. The first professional explanation to suggest itself would be bound up in a reflex mechanism, but the fact that warts are clearly due to contagion tends to invalidate such a supposition. At a recent session of the Aertzlicher Verein of Hamburg Delbanco (*Deutche medizinische Wochenschrift*, September 5) stated that he had had under treatment a young woman with numerous hard warts of both hands, especially massed about the joints, which rendered curettage inexpedient, since general narcosis would have been necessary. Despite the fact that the *x*-ray was not a dependable resource the author gave it a trial, limiting the first sessions to the right hand. The warts soon began to show evidence of involution not only on the right hand but on its fellow as well. Both hands became free at the same time. At least two specialists, Wälsh of Prague and Galewski of Dresden, have seen this crossed result follow curettage on one side. Delbanco names three possibilities to explain the disappearance of the warts on the untreated hand. First coincidental spontaneous disappearance which can almost be excluded from consideration; second, the reflex, angioneurotic theory (Kreibich), and third, an immunizing or lytic process occurring purely through the circulating blood.

Dysontogenesis and Cancer.

One of the most striking truisms in medicine, one which is verified daily, is the necessity of cumulation of causal elements to produce a pathological state. This is so self-evident that it is often ignored; realization of it should do much to discredit one-cause hypotheses of disease, such as are constantly in evidence in nonprofessional minds. The "cause-all" is a fitting companion to the "cure-all." Ernst at a meeting of the Naturhistorisch-medizinischer Verein of Heidelberg (*Muenchener medizinische Wochenschrift*, July 16) calls attention to the dysontogenetic element which may underlie cancer. The embryonal theory of cancer is of course very old, and the existence of branchogenous cancer and similar forms associated with congenital anomalies was largely responsible for Cohnheim's "misplaced residue" hypothesis. The author goes no further than to call attention to certain cancers in which such obvious factors as chronic irritation and atrophic change are not concerned. In an individual with profound dysontogenesis of the central nervous system and urinary apparatus an epidermoid cholesteatoma of the angle of the pons cerebelli was found to be the starting point of a carcinosis so widespread that it extended over the meninges and ventricles and descended down the spinal canal as far as its lumbar portion. No primary focus was found. The parasitic theory and irresponsible cell growth theory do not necessarily exclude each other nor do they exclude the dysontogenetic theory. Individual competitive theories often resolve themselves into so many distinct causal elements.

News of the Week.

Herter Lectures.—Prof. Max Rubner of the University of Berlin will deliver five lectures on "Energy Problems in Nutrition" under the Herter Foundation at the Carnegie Laboratory, 338 East 26th Street, New York, beginning on Monday, October 7, at four o'clock, and continuing daily at the same hour.

Harvey Society.—Prof. G. H. F. Nuttall of Cambridge University, England, will deliver a lecture on Saturday evening, October 12, at the New York Academy of Medicine, on "The Relapsing Fevers," before the Harvey Society.

College of Physicians and Surgeons.—At the opening exercises of the college which were held on Wednesday, September 25, an address of welcome was made by Dr. Butler, president of Columbia University, after which Dr. Theodore C. Janeway, Bard professor of medicine, spoke upon "The Importance of Pathological Theory for Practical Medicine." The college opened with a registration of 323 students, divided as follows: First year, 87; second year, 68; third year, 71; fourth year, 93; special, 4.

Civil Service Examinations.—The United States Civil Service Commission announces the following examinations: On October 23, an open competitive examination for the purpose of filling two vacancies in the position of medical interne in the Government Hospital for the Insane at Washington, at a salary of $600 per annum with maintenance.

On the same date an examination will be held for the purpose of filling five vacancies in the position of dentist at $1,500 per annum, in the Indian Service at large. The incumbents of these positions are also allowed actual and necessary traveling expenses, subsistence, and incidentals while on duty in the field. Applicants must be graduates of a regularly incorporated dental college, and have at least two years' experience in the practice of dentistry subsequent to graduation.

An examination, open to men only, will also be held on that date for a vacancy in the position of dental interne at $600 per annum in the Government Hospital for the Insane at Washington, with maintenance.

Full information and application blanks may be obtained from the United States Civil Service Commission, Washington, D. C.

Medical Colleges Open.—The College of Medicine of the University of Vermont, Burlington, opened on September 25 with an enrollment of 142 students. The requirement of one year of college work before entrance, which went into effect this year, has had a marked effect on the entering class, which numbers only 12, in comparison with 46 last year. Dr. Frederick W. Sears has been appointed lecturer in nervous disease, and Dr. Barnet T. Joseph librarian of the medical library.

The University of Pennsylvania began its 173d year on September 27 with a record number of students. In the Department of Medicine Dr. William Pepper assumed the office of dean, succeeding Dr. Allen J. Smith, who resigned in order to devote his entire time to his work as professor of pathology.

Smallpox in the United States.—During the year 1911 smallpox was prevalent all over the United States, but in a very mild form, according to the public health reports. Severe outbreaks of the disease during the year were limited to Texas, Californonia, and Kansas, and were few in number. Reports from twenty-nine States and the District of Columbia give a total of 21,768 cases during the year and 134 deaths reported. In 1910 there were in these same States 25,598 cases, with 403 deaths. The greatest number of cases were reported from North Carolina, 2,484; Florida, 2,195; Kansas, 2,043; Utah, 1,660, and Colorado, 1,381. In Connecticut only two cases were reported during the year. The case fatality was, on the whole, very low, the average rate being only 0.61 per 100 cases. In Massachusetts, however, there were 11 cases, with two deaths, giving a fatality rate per 100 of 18.18, the highest reported. In Texas, where many more cases of the disease occurred, the rate was 7.42, and in California 5.4 per 100.

The Plague Situation.—Four cases of plague were reported at La Perla, San Juan, between September 1 and 12, but the focus from which the infection in all these cases was undoubtedly received has been eradicated, and no more cases are expected to develop. No new cases have been reported in Havana. In Manila, P. I., four cases were reported during August, and in Hawaii one fatal case was reported on September 10, the first human case since March 14.

Epidemic Poliomyelitis.—The outbreak of infantile paralysis which began in Buffalo, N. Y., in June has not yet subsided, although it is apparently under control. During the week ending September 14 there were reported 18 cases, making a total up to that time of 226 cases, with 30 deaths. Unusual numbers of cases of the disease have also been reported in other places in the vicinity of Buffalo, and at Batavia, Genesee County, 14 cases have occurred during a few weeks. The epidemic at Los Angeles, Cal., seems, on the contrary, to be at an end. The outbreak there began in June also, and up to September 7 there had been reported 249 cases. The subsidence of the disease followed closely upon the establishment of a rigid quarantine of premises where there were cases, the closure of schools, and the prohibition of gatherings of large numbers of children.

City Death Rate.—During the week ending September 21 there were 1,162 deaths in New York City, while for the same week of last year the total was 1,330, the rates per thousand being 14.51 and 15.76 respectively. Of babies under one year of age there were 313 deaths last week, making a total so far this year of 587 deaths less than during the same time last year.

X-Ray Victim.—The French Government will, it is reported, shortly offer a decoration through the Minister of the Interior to Mlle. Weidemann of Paris, said to be one of the first victims of the *x*-rays. Mlle. Weidemann was in 1898 employed in the radiographic laboratory of one of the Paris hospitals and as the result of injuries then sustained has lost both hands.

188th Aviator Killed.—By the death of Lieut. Gegazzoni of the Italian Army, who was crushed by the falling of his aeroplane on September 25, the number of aviators who have lost their lives has increased to 188. Of these 184 were men and 4 women. So far this year 78 persons have been killed in aeroplane accidents.

Obituary Notes.—Dr. Edmund F. Steckel of Allentown, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1862, and a veteran of the Civil War, died at his home on September 19, aged 72 years.

Dr. Edwin W. Trueworthy of Lowell, Mass., a graduate of the University of Vermont, College of Medicine, Burlington, in 1865, a veteran of the Civil War, and a member of the Massachusetts State and Middlesex County Medical Societies, died at his home on September 13, aged 73 years.

Dr. Frank Wallace Brett of South Braintree, Mass., a graduate of the College of Physicians and Surgeons of Boston, in 1894, a member of the American Medical Association, and the Massachusetts State and Norfolk County Medical Societies, died suddenly at his home on September 1, aged 51 years.

Dr. George W. Butts of Chuckatuck, Va., a graduate of the Winchester Medical College, Va., in 1868, a member of the Confederate Army during the Civil War, and for eighteen years president of the Board of Visitors of the Deaf, Dumb, and Blind Institute at Staunton, died suddenly on September 6, aged 70 years.

Dr. Francis L. Frost of Charleston, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1861, and a member of the Confederate Army during the Civil War, died at his home on September 4, aged 81 years, aged 26 years.

Correspondence.

THE FIFTEENTH INTERNATIONAL CONGRESS ON HYGIENE AND DEMOGRAPHY.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 581.)

LIGHTING OF THE IDEAL SCHOOL—MORTALITY AND THE CAUSES OF DEATH BY PROFESSIONS—THE HOSPITAL SHIP—FIRST AID IN SEA BATTLES—CAMP SANITATION—GAS POISONING ON SHIPBOARD—HYGIENE OF THE ENGINE ROOM—INGESTION OF FOOD AND METABOLISM—FOODSTUFFS AND METABOLISM—NUTRITION AND BONE GROWTH—RÔLE OF PROTEINS IN GROWTH—THE OCCUPATION NEUROSES—A NEW LENS TO CORRECT SIGHT DEFECTS—CAISSON DISEASE—EXPOSURE TO INTENSE HEAT—INJURIES CAUSED BY ELECTRICITY—DEVELOPMENT OF VITAL STATISTICS IN THE UNITED STATES—BIRTH STATISTICS—RELATION OF RURAL AND URBAN POPULATIONS—CLASSIFICATION OF THE CAUSES OF DEATH—THE TRAINING OF DEMOGRAPHERS.

WASHINGTON, D. C., September 24, 1912.

M. AUGUSTIN REY, a Parisian architect, described his ideal school. He said that the beneficial effects of the violet rays were so well known that it was criminal to build in such a way that they could not penetrate to every part of a room; it was doubly important that this should be possible in school rooms. If there was a choice between heat, ventilation, and sunshine we should see that we had the sunshine first. His building was so arranged that the classes should meet in the east rooms in the afternoon after the morning sun had thoroughly disinfected them and in the west in the morning, since the afternoon sun would have disinfected the western rooms on the previous day. There should be plenty of ground and plenty of sand about school houses. It is better to economize in decorations than in sunlight and ventilation. "Speculation in land must be stopped. Speculation in land in our cities is a crime against society." He said that while this was his ideal school he preferred the open-air school.

The second and last address delivered in the General Session was on "Mortality and Causes of Death by Professions" by Dr. Jacques Bertillon, chief of the Bureau of Municipal Statistics, Paris, France. He compared, by countries, the mortality of each profession to the average mortality of the country. He said when mortality in a profession is inferior to the general average during youth, and on the contrary exceeds the average at mature age, and when we find these same results in several tables we can deduce that this profession is injurious to health. We must investigate what diseases cause these results. We must, therefore, for each profession, calculate the frequency of each disease at each age. To obtain from this multitude of figures general conclusions, it is indispensable to classify the professions from a hygienic point of view. Authors who have undertaken this classification have merely remembered professions affected by some extraordinary disease, such as malignant pustule among tanners, lead colic among painters, etc.; they remembered, besides, the etiology ordinarily attributed to some common diseases, such as humidity for rheumatism, cold for pneumonia, dust for tuberculosis. And it is from this information that professions have been classified. This method is the best to be followed when there are no statistical data. It is, however, very imperfect; it gives too much importance to certain professional diseases which incur very few deaths. Moreover, it prejudges *what is probable,* instead of being based *on fact.* The speaker proceeded quite differently. Taking statistical facts as a basis, he has classified the professions according to the rarity, moderate frequency or frequency of phthisis. In each of these three divisions he has distinguished three groups according to the degree of frequency of other diseases of the respiratory system. In each of these nine groups he has made three sub-groups according to frequency of heart diseases, and so on, successively considering the frequency of liver diseases, of nephritis, of diseases of the nervous system, more particularly after the fortieth year; that is to say, when the profession has had the time to exercise its good or harmful influence. This led the speaker to make 729 sub-groups of professions. Professions then group themselves so naturally that it is, in spite of its appearance, rather easy to summarize this immense table of 729 divisions. He came thus to classify them as follows: A. Groups of professions in which phthisis is generally frequent or rather frequent. These professions may be grouped as follows: Professions exposing men to alcohol (wine merchants, brewers, etc.); saturnine professions; professions exposing to changes of weather and compelling the operative to rest (coachmen, cart-drivers, etc.); different journeymen (since these professions are all alcoholic and suffer great mortality caused by all diseases); metallurgy; textile and similar professions; professions exposing man to organic waste. These divide themselves into sub-groups: professions where there is little or no dust; professions exposing men to hard dusts of animal origin, and professions exposing men to hard dusts of vegetable origin; professions generally performed in confined places; servants. B. Professions where phthisis is rare, but liver disease frequent or moderately frequent: liberal professions (priests and professors separate themselves from the other liberal professions by the rarity of liver and kidney disease. One is surprised to see these diseases so frequent in England, where one would believe these professions free from intemperance). C. Professions where liver and kidney disease are rare. Professions exercised in the open air without constraining to agricultural rest. These are divided into four sub-groups: agricultural professions (here all causes of death are rare); industrial professions (caissons, lime burners, boat constructors, railroad engineers, etc., are somewhat less favored than the preceding group); professions performed on the water (here one notices the frequency of heart disease and accidents); traveling salesmen; wood workers; miners; chemical industries or similar. Dr. Bertillon exhibited numerous diagrams and charts, some devoted to the study of a single profession and some to the study of a single disease.

In the Military, Naval, and Tropical (Colonial) Hygiene Section, Surgeon-General Charles F. Stokes, U. S. Navy, read a paper on "The Hospital Ship, a Component Part of the Fleet and the Repair Ship for the Personnel." To insure the highest degree of military efficiency in time of peace and war, a hospital ship should be a component part of the battle fleet at all times. Not only is the hospital ship the repair ship for the personnel of the fleet,

but it is, as well, a scientific unit aiming, by means of chemical, bacterial, and other specialized work in medicine and surgery, to uplift the military effectiveness of the fighting forces. The hospital ship is the meeting place for the officers of the fleet, where problems in sanitary administration can be discussed and unified, clinical demonstrations made, and papers in naval medicine and surgery read and discussed. The hospital ship should carry the medical reference library for the fleet. In time of war the medical transport supplants the hospital ship in its importance to the fleet in operations at sea. In naval operations on shore, the hospital ship would act as a base hospital and as a supply ship.

Dr. Stokes also read a paper on "Dressing Stations, and Transportation of the Wounded in Battle at Sea." He believes that dressing stations are of little use except when a ship acts singly. The transportation of the wounded from one part of the ship to another part of the same ship is considered undesirable. The wounded should lie where they fall, there to be treated by a sanitary personnel from a fleet of medical transports, afterward removed to the medical transports, and thence to a sanitary base.

Surgeon-General Dr. A. Bornemann, R. N., Denmark, read a paper on the "First Treatment of Wounded in Sea-Battles." He said that in the Russo-Japanese War a number of the men were taught samaritan work. In the Danish Navy this work had been further perfected. The men as well as the officers are instructed: (1) In the first-aid treatment of wounds; (2) in the methods of temporary control of hemorrhage; (3) in the principles involved in moving wounded from one place to another with the hands alone, and how to place the wounded in the best possible position. At the same time there has been introduced a one-man bandage so prepared that it will remain absolutely sterile as long as it is dry. A water-proof cover protects it against perspiration. It is so arranged that when it is opened it can be at once placed on the wound without being soiled by the hands. The men carry it in an inner pocket of their outer garments. Further depositories for bandages are arranged in the various places where the crew is stationed. By employing these precautionary measures the author regards it as probable that in every battle some of the wounded who would otherwise perish will be saved.

Marine-Generaloberarzt Dr. Heffman, Berlin, Germany, presented a paper on "Hospital Quarters for the Wounded in Battle, and Transportation of the Wounded on Board the German Warships," Médecin-en-chef de la Marine française, Dr. P. Barthélémy, médecin de division, Croiseur cuirassé "Leon Gambetta," France, read a paper on "Dressing Stations and Transportation of Wounded in Battle at Sea." Surgeon-General Dr. Simon von Unterberger, Privy Councilor, Hon. Physician to his Majesty's court, St. Petersburg, Russia, read a paper on the "Permanent Camp of Krassnoje-Sselo from a Sanitary Point of View." The village of Krassnoje-Sselo (Red Village) was used as a camp for the first time in 1765; the number of soldiers now amounts to about 40,000. This camp is a most excellent one. Owing to the constitution of the lime, the sand, and the blue clay, the camp has beautiful, clear drinking water from springs with radioactive qualities. Joseph H. Ford, Major, Medical Corps U. S. Army, Canal Zone, read a paper on the "Disposal of Wastes," giving a succinct description of the apparatus employed for the disposal of wastes in camps. Papers on Water Supply were read by Lieut.-Colonel Charles F. Mason, Medical Corps, U. S. Army, Washington, D. C., and Major Carl R. Darnall, Medical Corps, U. S. Army, Washington, D. C.

Marine-Oberstabsarzt Dr. Weber, Berlin, Germany, presented a paper on "Some Cases of Gas-Poisoning Frequently Occurring on Board." The object of this lecture was to draw attention to the deficiencies existing in literary works bearing on the subject which have been apparently neglected hitherto; also to interest a large number of technical men so that they may cooperate in solving problems that may in the future come to the front in connection with this important subject.

Surgeon F. L. Pleadwell, U. S. Navy, presented a paper on the "Hygiene of the Engine and Fireroom Force with Special Reference to the Effects of Heat and Humidity." Surgeon R. C. Holcomb, U. S. Navy, read a paper on the "Hygiene of Engine and Fireroom Force." The object of this paper was to show that the prime duty of a battleship is to meet battle conditions. That, to meet these conditions, air supply alone is inadequate, and that proper ventilation is not established unless both supply and exhaust systems are furnished. Oberstabsarzt Dr. Hüne, Stettin, Germany, read a paper on "Bacillus Carriers Under Military and Naval Conditions." Médecin-Inspecteur General Dr. Fevrier, France, ministry of war, read a paper on "Purification de L'eau, Destinée aux Troupes en Campagne."

In the Section on Dietetic Hygiene and Hygienic Physiology Dr. Francis G. Benedict, director of the Nutrition Laboratory of the Carnegie Institution of Washington, Boston, Mass., read a paper on the "Influence of the Ingestion of Food upon Metabolism." Three interpretations of the increase in metabolism following the ingestion of food are current, first, the theory in which the mechanical work of the digestive processes plays the most prominent rôle; second, the less sharply defined theory in which the conception of the development of free heat unavailable to the cells is the dominant note, and, finally, the opinion expressed by Friedrich Müller, that there are absorbed out of the blood certain substances which are carried by the blood to the cells and there stimulate the cells to a greater metabolic activity. The evidence used for the evaluation of these views in his paper was based almost exclusively upon experiments made upon men. From the evidence it suggests that coincidental with what is commonly termed a "state of acidosis" there are present in the blood a body or bodies, probably of an acid nature, that stimulate the cells to a greater metabolism.

Dr. Graham Lusk of New York presented a paper on the "Influence of Foodstuffs and their Cleavage Products upon Heat Production." If meat in large quantity be given to a dog, the heat production rises in the second hour almost to its maximum, reaches its maximum in the third hour and continues at this level though the tenth hour when it begins to fall. In one instance the heat production during a morning hour was 22.3 calories, and after the ingestion of 1,200 grams of meat it had risen in the second hour to 36 calories, reaching 40 calories in the third hour at which level it remained through the tenth hour, after which it gradually fell to 25 calories in the twenty-first hour. During the second hour the nitrogen elimination was one-third the maximal nitrogen output as evenly maintained between the third and tenth

hours. The second hour also showed that the calculated non-protein respiratory quotient ranged between 90 and 99, which indicated that that part of the metabolism which was not due to protein as calculated from urinary nitrogen, originated largely from carbohydrate. During the later hours, the increased heat production is proportional to the nitrogen in the urine. During a period of 15 hours, protein carbon was retained in the organism and when the oxygen absorption as computed on the basis of such retention in the form of dextrose, is compared with the actual oxygen absorption, the two agree within 0.9 per cent., whereas computed on the basis of carbon retained as fat, there is a discrepancy of 10 per cent. between the calculated and actual value. The administration of 50 grams of dextrose in 150 c.c. of water to a dog, causes a rise of heat production from 16.2 to 20 calories, at which level it is maintained during the second, third, and fourth hours, falling nearly to the basal level in the fifth hour. The skin temperature rises to a greater extent than the rectal temperature. The absorption from the intestine is completed in the fourth hour. The urine is scanty until the fourth hour when 100 c.c. is suddenly eliminated. The sugar content of the blood in per cent. rises in the first hour but becomes normal after that. After the first hour the percentage of hemoglobin in the blood falls but returns to normal subsequent to the fourth hour. Hence, after sugar ingestion, osmotic phenomena cause an increased volume of blood. When the absorption is complete, the glycogenic function removes the dextrose from the blood, and the blood returns to its normal composition through the elimination of water by the kidney. Water alone or a solution of salt or of urea has no effect on the metabolism, hence the increase in metabolism is probably due to the increased number of molecules of dextrose carried to the cells and not to changes due to osmosis. Liebig's extract of beef is without influence on the metabolism. Fifty grams of olive oil causes a considerable increase in heat production. Glycocoll causes a very great increase in heat production, alanin also acts powerfully, leucin and tyrosin less so and glutamic acid not at all. It is concluded that the heat production may be increased by increasing the quantity of sugar and fat reaching the cells, or it may be increased through the direct stimulation of the cells by amino-acids, notably glycocoll and alanin.

Dr. Francis H. McCrudden, chemist to the Rockefeller Institute for Medical Research, New York, read a paper on "Nutrition and Bone Growth." Bone, like other tissues, undergoes metabolism throughout life. Old bone is continuously being reborbed and new bone laid down. If the new bone laid down is not qualitatively of the right composition, the result may be rickets, osteomalacia, osteoporosis, or osteitis deformans, depending upon the age of the patient and other factors. The bones act as a store for lime salts to be called on in time of need just as the subcutaneous tissue acts as a store for fat and the liver as a store for glycogen; and a flux of calcium from the bones started by a growing fetus, a hardening callus, metastatic bone formation, etc., may, under certain circumstances, lead to decalcification enough to result in osteomalacia and similar conditions. An important factor is the degree to which overproduction takes place, a factor involved also in immunity and, in fact, in all tissue repair. There were other disturbances which may be said to involve quantitative disturbance in bone growth, the rate of growth, rather than disturbances in the qualitative character of the bone produced. In some of these the failure to grow seems to depend on an absence of the "growing tendency" on the part of the bones; in others, some disturbance in the supply of lime salts available for bone growth seems to be at fault.

Dr. Lafayette B. Mendel, professor of physiological chemistry, Sheffield Scientific School of Yale University, New Haven, Conn., read a paper entitled the "Rôle of Proteins in Growth." He believes that some of the views held in the past regarding the interrelation of the food supply and growth are no longer tenable. Growth has often been associated in a causal way with the relative abundance of protein in diet. The parallelism between the protein content of milk of various species and rate of growth may be an example of correlation rather than of causation. Recent investigations have shown that the assumed association of growth with high protein intake is not confirmed by the evidence at hand. Growth is a function of the cells. This inherent capacity apparently cannot be exaggerated by feeding; but growth can be held in abeyance by various conditions. The development of a successful method of investigation by Osborne and Mendel has made it easy to approach some of the problems experimentally.

In the Section on Hygiene of Occupation Prof. Dr. L. v. Frankl-Hochwart, K.K. Universität, Vienna. Austria, read a paper on the "Occupation Neuroses." By occupation neurosis is meant a disturbance of the muscular innervation, which only sets in after a complicated activity of the muscles acquired by practice while the muscles in every other action obey the will. The differential diagnosis comes into consideration in a great number of other nervous diseases, viz., the cerebrospinal diseases, the tremors, tics, chorea, certain neurasthenic hysterical conditions (phobias, brachialgia, etc.), and intoxications. The just mentioned conditions are quite frequently confounded with professional neuritis, with true neuralgias (cramps), paralysis, atrophy, as observed after habitual monotonous work. Differential diagnosis is of special importance in angioneurosis (acroparesthesia), in dysbasia angiosclerotica, and in local diseases of the muscles, joints, tendons, and periosteum. True neurosis is mostly observed in men between the ages of twenty and forty years. As etiological factors one must consider the nervous heredity, the neuropathic diathesis, insufficient alimentation, alcoholism, and nicotinism. Professional overwork is one of the main factors; depressing conditions of life and the effect of fright are also predisposing factors. The symptomatology is best observed in the most frequent and most important neurosis: in writers' cramp. One must differentiate between four forms: (1) The spastic; (2) the paralytic (ataxia); (3) the tremor-like, and (4) the neuralgic. One occasionally finds as accompanying symptoms a slight weakness of the muscles and indications of disturbances of sensation. Those whose professional occupation is drawing and painting, and the stenotypists also, acquire the disease in the same manner as the copyists. Quite frequently one observes the neurosis of the upper extremities in musicians (pianists, violinists, buglers, etc.). In the latter one can observe disturbances of the innervation of the lungs and of the lips. To this group also belong the different varities of the vocal disturbances of speakers and actors, and of officers, caused by

habitually giving orders in a loud voice, and the neurosis of the voice caused by singing. Cramps are also observed in seamstresses, tailors, and persons engaged in similar occupations, also in barbers, in people who handle heavy hammers, in those who milk cows, in typesetters, in telegraphers, in cigar wrappers, in waiters, diamond cutters, cashiers, chauffeurs, etc. Sometimes similar conditions are observed in the lower extremities, for instance, in dancers, in those who while working use only one foot to turn a wheel, such as lathe workers, scissors grinders, bicyclists. In addition to the above mentioned cramps of the buglers, speakers and singers, there have been observed a few cases of cramps of the muscles of the head and of the neck; for instance, characteristic contractions while reading, also cramps of the eye muscles in microscopic work, in military drill, and in reading notes. Prognosis is not absolutely bad, but always doubtful. Recurrences are frequent. Everything which strengthens the individual psychically and physically will tend to prevent this neurosis. It is important to exercise the muscles in some way other than the habitual one; it is also important to insure instruction in manual work to prevent improper working habits. Overwork is harmful also, especially in early youth. The most important points in the treatment are: Cessation of all work which provokes the cramp, the adoption of general measures which have a beneficent effect on the general health; hydro-(thermo-)therapy, radiotherapy, electrotherapy, gymnastics, massage. In several instances writing apparatus was constructed; important are practical exercises in writing under the instruction of experts, also psychical re-education; after all psychotherapy seems to be the main factor in the treatment of this disease.

Dr. Louis Casamajor, New York, read a paper on "An Unusual Form of Mineral Poisoning Affecting the Nervous System" and questioned whether it was manganese. Dr. George M. Gould, Atlantic City, N. J., read a paper on "Eyestrain and Occupational Disease"; the evil effects of eyestrain are ignored by nearly all investigators, a convincing example being, in his opinion, the origin of myopia. Dr. G. Carlo Precerutti, Turin, Italy, presented a New Lens to Correct the Usual Defects of Sight. This lens was not only able to correct the usual defects of sight, but to prevent the serious alterations of the transparent media and of the bottom of the eye, in fact, cures them when they have begun, and augments the visual strength. In the lens has been embodied a radioactive substance dosed in such a way that through constant use the emanations are utilized, thus establishing a true cataphoric action on the organs of sight so that the lens corrects and cures at the same time.

T. Kennard Thomson, honorable vice-president of the American Society of Mechanical Engineers, New York, presented some notes on "Caisson Diseases," showing that sewage polluted soil in the Harlem River caissons caused much trouble with caisson disease at light pressure of compressed air which in pure air would have given no trouble. Also air rendered impure by workmen caused trouble and New York was taking great risk by polluting its rivers and bays. Dr. Seward Erdman, New York, described the acute effects of caisson disease and reported an analysis of the gas obtained from the right heart at autopsy. Dr. Peter Bassoe, Chicago, told of the "Remote Effects of Caisson Disease"; his paper mainly consisted in a further elaboration of the material investigated under the auspices of the Occupational Disease Commission of Illinois during the year 1910. The most common persistent results seemed to be deafness and tinnitus. Attention was called to the large number of men giving histories of paralysis and other serious manifestations years ago and now well and free from physical signs of disease. Alcoholism was very prevalent among the men who were studied.

"Caisson Disease and Its Prevention" was considered by Henry Japp, member of the Institute of Civil Engineers and of the American Society of Civil Engineers, New York City, in which he stated that our ignorance of caisson disease in the past has resulted in an increasing cost of operation by bringing about reduced hours of labor to minimize the chances of disease, by increasing wages to overcome the fear of disease, and by limiting the supply of labor through medical exclusion to prevent disease. Without doubt men are built to undergo pressure changes, as it is possible on the earth's surface to experience a range of pressure from 17½ pounds absolute in the deepest mine to 5 pounds absolute on the highest mountain, or a fall of 71½ per cent., which is the equivalent of decompressing from + 36¾ pounds to atmosphere. Paul Bert's mechanical theory that caisson disease is caused by the blood and tissues absorbing nitrogen under pressure, which escapes as bubbles during and after decomposition, is generally accepted, and cure by decompressing the liberated bubbles and prevention by slow decompression are universal. E. W. Moir's medical airlock on the Hudson Tunnel reduced the death-rate from 25 to 1 per cent., and on the New York East River tunnels this, combined with slow decompression, gave a death-rate of .19 of 1 per cent. Dr. Haldane's stage decompression method prevents fatal cases, and provides safety for divers in 210 feet of salt water, or + 92.4 pounds. This method consists of never permitting the maximum air saturation of the body on decompressing to be higher than 2.3 times the pressure in the airlock or than the atmosphere on emerging. This permits a quick drop to half the absolute pressure on entering the airlock, which accelerates the desaturation of the body much more quickly than the uniform method of decompression. In very deep diving, where the period of immersion is not great, the decompression period is not excessive, but in caissons and tunnels the immersion is comparatively long and the decompression period required appeared to the speaker to be too conservative and lengthy for practical purposes. On the East River tunnels 23,000 individual compressions were made from + 40 pounds, with a modified stage method on Dr. Haldane's principle, in forty-eight minutes without fatal or serious cases, leaving the maximum air saturation of the body on emerging at + 27 pounds. From this result the speaker has drawn up a table for decompression from tunnels. The methods of caring for the workmen were described and the regulations under which they worked were embodied in an appendix, as well as the proposed rules to be observed, which were submitted to the Commissioner of Labor of the State of New York by twenty-one engineers, doctors, and contractors.

The effect of the workmen's mental condition was mentioned as a possible influence on their susceptibility to caisson disease, just as fear is said to make men subject to yellow fever. Dr. Leonard Hill's conclusions from his recent experiments were given, and the desire was expressed that the Inter-

national Congress on Hygiene and Demography should draw up a table for decompression as a guide to future legislation.

A paper on "Prophylaxis of Labor in Compressed Air" was read by Dr. Herman von Schrötter, Vienna, Austria, in which he stated that the experimental results of recent years have enabled us to understand better the pathogeny of the various symptoms observed after rapid decompression. We have also more correct conceptions in regard to the rôle of oversaturated liquids, and of the conditions under which the release of gases in bubble form takes place in the organism. The decompression must take place, so that, while more rapid in the beginning, it slows down gradually and in proportion to the degree of saturation. In all cases a decompression in the contrary sense seems injurious. The muscular work facilitates, by its effect on the circulation, the elimination of gas during (and after) the discharge. Oxygen as a prophylactic and therapeutic means should, according to what we have already at another time insistently advised, enter more strongly into the practice of decompression. The use of oxygen could shorten the necessary duration for effecting a decompression unattended by danger. *Duration of Stay and Decompression.*—After labor under an overpressure of 1-1.5 atm., which need not be limited as to time (that is, 6-8 hours' shift is not too long), decompression may be effected in 10, that is, between 5-15 minutes, in which latter case initial acceleration of the decrease of pressure appears proper; after labor under an overpressure of 2 atm., decompression to 0.5 atm. in 3 minutes. Overpressure should be effected and then at an even rate of 0.1 atm., in not less than 4 minutes. After labor under an overpressure up to 3 atm., work must be shortened to 3.4 hours. Concerning decompression: the first decrease of pressure should occur in 3-5 minutes to 1.5 atm. Employ overpressure, then decrease the pressure at the rate of 0.1 atm., in not less than 4 minutes, or gradual decompression by means of an airlock, with about one-half, then one-quarter of the working pressure, with regard for physical activity, avoiding of harmful refrigeration (use of oxygen). In every construction work in which an overpressure of 1.5 atm. is employed, there must be a recompression airlock. How to arrange the prophylactic measures in each individual case depends upon the particular circumstances of the work, upon the requirements which labor in compressed air demands. In the technical preliminary measures for a construction to be built under compressed air, a physician, well versed in the matter, should therefore be consulted who, on the basis of the technical and local elements entering into the work, should determine the special regulations, based on the facts established, and correctly harmonize stay, pressure and decompression in order to reduce, as far as possible, the quota of danger. These, in such case obligatory measures shall from the begining have to be arranged in such a way that they will take into account the possibility of a wider basis as the work progresses, etc. The slow decompression, with a rapidity accelerated in the beginning as proposed by Haldane is preferable to a uniform decrease of pressure. Oxygen as a prophylactic agent should be used more than heretofore, especially in the case of the diver.

"The Effects of Exposure to Intense Heat on the Working Organism" was described by Dr. David L. Edsall, Harvard Medical School, Boston, Mass., a condition which he described some three years ago. The condition was characterized chiefly by muscular spasm, extremely common in some occupations, and seemed to occur during hot weather and chiefly in those regions where the summer temperatures rise quite high. Economically it has at times considerable importance in interfering with the efficiency of the working force. Occasionally the attack is fatal. Improved ventilation and the substitution of cranes and other mechanical appliances for manual labor in the heaviest and hottest parts of the work are the chief available preventive measures. The treatment is mainly symptomatic in controlling pain. Surgeon Charles N. Fiske, U. S. Navy, Washington, D. C., said that sunstroke was rare in the navy, but heat exhaustion may have either systemic shock or local muscular spasm predominating. The etiological factors with which the hygienist has concerned himself are chronic alcoholism, dissipation, debility, hard muscular labor, unrelieved fatigue, lack of sleep, insufficient circulation of air, wet bulb temperature above 85° F., lack of habituation, unsuitable clothing, fright, excess of protein and deficiency of carbohydrates in diet, insufficient assimilation of water, blood concentration, corpuscle destruction and arterial anemia, diminished toxin elimination through excess of cutaneous over renal excretion, predisposition from former attacks and others less likely.

Dr. Wilhelm Lindemann, Sanitätsrat, Bochum, Germany, read a paper on "Accidents and Diseases of Miners and Tunnel Workers," in which he stated that the most important hygienic measure for the prevention of ankylostomiasis is the use of transportable toilet-seats.

Sir Thomas Oliver, University Durham College of Medicine, Newcastle-upon-Tyne, England, read a paper entitled, "Injuries Caused by Electricity." We are constantly being reminded of the deadly effects of electricity. Contact with a live wire or an unprotected portion of machinery may kill a person immediately, it may injure him so severely that he dies in a few hours afterwards, or he is severely burned and recovers slowly. Death in electric shock resembles death caused by lightning. It is difficult to say what pressure electrical current or voltage is within the limits of safety. Of the two kinds of current the alternating is more dangerous than the constant, when the values are not too high. Currents of 100 to 150 volts are generally regarded as within the limits of safety, 200 to 300 as coming within the danger sphere and anything above 600 as likely to be fatal. There is no absolute certainty in this statement however. Mode of contact, duration of contact and whether made with one or both poles, the condition of the skin at the time, *e.g.* moist or dry, state of boots a workman is wearing and whether the soil is moist or dry, are circumstances which determine the consequences of exposure to electrical currents. The skin of the body offers resistance to the penetration of the current. When an electrical current penetrates the skin, none of its energy is lost; it is simply transformed into mechanical, thermal, chemical and electrolytic action. The injuries caused by electricity can hardly be regarded as burns, since they are not wholly due to extension from the surface but to internal heat. Cases of injury which came under personal observation were described in association with Professor R. A. Bolam; the author carried out a series of experiments with the view of ascertaining the causes of death in electric shock. In most of the animals death was due to

the arrest of the heart's action. Prevost and Battelli of Geneva found that currents of low tension cause death by the heart becoming paralyzed; with currents of high tension the breathing is first arrested, the animal is killed outright by inhibition of the respiratory center. Grange is of the opinion that hemorrhage into the medulla oblongata causes death by pressing upon the origin of the pneumogastric nerve. Jellinek found on lumbar puncture evidence of high cerebrospinal pressure in death after electric shock. He too is of the opinion that death is usually due to stoppage of the heart. In many experiments heart and respiration cease together, or respiration may be first arrested. Burns and the effects of electrical sparking upon the eyes are considered, also the methods of treatment to be adopted for the restoration of persons apparently killed by electricity.

"Diseases and Injuries Occurring in Electric Plants" was the title of the paper read by Dr. J. D. McGowan, Surgeon, Commonwealth Edison Company, Chicago, and it was his belief that the electric current *per se* does not cause any disease. "Accidents and Diseases of Ironworkers" was the title of a paper read by Dr. Friedrich Röpke, Solingen, Germany. In prophylaxis the guiding principle is: dust or gases must be rendered innocuous at the place of their origin. He had observed a few cases of mercurial poisoning among the fire gilders in the sword industry.

(To be continued.)

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COMING SESSION—BRITISH ASSOCIATION—SECTIONAL PROCEEDINGS AND GENERAL DEBATES—MIND AND MATTER—ORIGIN OF LIFE—ISOLATION HOSPITALS—OBITUARY.

London, September 13, 1912.

The opening of the medical schools for the winter session is already the subject of conversation and those in any way connected with teaching are comparing notes of the arrangements made for keeping the traditional 1st of October at their several institutions.

Sir T. Crosby, the Lord Mayor, will take the chair at an old students' dinner of his own school of St. Thomas' Hospital. The occasion is to be marked at the London Hospital by the Schorstein memorial lecture to be delivered by Prof. Wardrop Griffith and in the evening a dinner will be held at which the venerable Jonathan Hutchinson has promised to take the chair and no doubt his surviving colleagues and numerous old students will put in an appearance. At the Middlesex Hospital the chief function will be the distribution of prizes; this will be conducted by Sir Charles Wyndham, who was originally educated for the profession and took the M. R. C. S. Eng. in 1857. The introductory address will follow by Dr. Lazarus-Barlow, and in the evening the inevitable dinner, when Dr. Campbell Thomson will take the chair. At Bart's a dinner in the great hall with Dr. Lewis Jones in the chair. At St. George's the introductory address by Mr. H. B. Grimsdale, whose subject is announced as "The Present Duty of the Medical Citizen," followed by the dinner, Dr. Penroe in the chair. At King's College Hospital the dinner is to suffice, presided over by Prof. Norman Dalton. At St. Mary's Dr. Gow will preside at the dinner, but earlier there is to be a distribution of prizes, when the Lord Mayor has promised to give a short address. Sir Rickman Godlee, president R. C. S. will preside at the University College Hospital dinner; Mr. Spencer at the Westminster. At Guy's the Pupils' Physical Society give their conversazione. At the Charing Cross Lady Mary Glyn and the Bishop of Peterborough will distribute prizes. At the Women's School Miss Jane Walker, M. D., will give the introductory, her subject, "Common Sense."

Members of the British Association have now returned, the meetings having concluded on the 11th inst. They seem to have enjoyed their trip, both the entertainments and the work of the sections. There were twelve of these and each with a chairman and his address. All sections were more concerned with pure science. Those most connected with medicine were physiology and chemistry, but even of these I can only mention a few points reported to me. In the former the president, Prof. Leonard Hill, talked of stuffy rooms, insisting that changes in the chemical composition of the air was not the cause of their evil influence and the specious standard of purity had deceived the public into permitting the elevation of skyscrapers and the sinking of cavernous places of business. Temperature, light, movement and relative moisture were the points to consider as to health. The monotonous lives of workers in such conditions while they continued would render useless sanatoria and dispensaries. Gas radiators and central heating were displacing the old open fires. The change improved the cleanliness and economized coal, but gave a monotonous, windless, warm atmosphere bad for the health. The efforts of engineers should be directed to cooling the air in public places and the bodies of people forming the audience.

There was a debate in this section on the "Relation of Mind and Matter," in which the hypotheses put forward by different schools of thought were more or less clearly described. But from what I can learn none seemed convincing and at the end Professor Starling declared the discussion had been a waste of time, a mere rehash of Thomas Aquinas complicated with incorrect physiology. Sir T. Clouston had argued that mental disease could be directly associated with alterations in the cerebral cells and that there were centers of mental inhibition which were nondeveloped in idiocy, imperfect in the primitive races and diseased in insanity. Dr. Haldane had contrasted the view that man consciously and purposively controlled, more or less successfully, his body through its environment, with the view that his conduct depended on that environment. If the former were adopted they were faced by the hard facts of the latter, adopting which the difficulty presented itself that mere physical and physiological processes could not offer an explanation of intelligent behavior.

In the chemical section, Professor Senier presiding, described their science as a complicated ideal structure of the imagination, a gigantic fairy palace, comparable to the wonderful stories of the "Arabian Nights." He traced some of the magical transformations of molecules and the conception of solid molecular aggregates and the hypothesis of isomeric phenomena. Passing to the practical education in the subject he urged that training in research should take precedence of elementary instruction, so far as national aid was given.

Two of the meetings of this section were held jointly with those of botany and zoology and were largely devoted to problems of growth and life.

One was notable for a discussion on plant pigments in which the chemists claimed equality with biologists in connection with the problems of heredity.

On Sunday there were official services in connection with the association at two churches, but the preachers only made indirect allusions to the proceedings. Canon Simpson urged the patient study of things as they exist and suggested that nature might be conquered by obeying it. Professor Denney told his audience that the Bible had not even a name for science, the purpose of Christ not being to anticipate knowledge but to reveal the Father. Science must be partial and its votaries marked off their boundaries and did not look beyond. There were doubtless references in other Protestant churches, but I have not heard of them. In the Roman Catholic one Rev. C. Widdowson directly controverted the presidential address. Sciolists in science and in religion were, he declared, the bane of both. That the fullness of being should shed out of itself all gradations of lesser and lesser was intelligible but that nothingness should endow the most majestic greatness revolted the sane mind. Yet they had been told evolution produced everything out of atoms and molecules. Emotions added nothing to flesh tremors; they might early find the atomic weight of toothache, the chemical composition of a sneer or the elements which combined to raise joy or grief. Surely they could not be expected to treat all that seriously. Monism itself was a revolt against such crude materialism. Physical science must ever remain impotent to fix finally the ultimate nature of things.

The debate of the week, fixed for Tuesday, was on the "Origin of Life," and, of course, embraced the presidential address; this is the subject which is always brought forward whenever the meeting is mentioned. Professor Minchin seemed to favor the view that the nucleus was the primordial form, as it was always present in living organisms; cells could not live when deprived of it, it was the first part to undergo division, was related to heredity and to ferments, and was the main part of the minutest organisms. When life appeared on the earth it was difficult to imagine how it could maintain its existence. Professor Wager thought that the previous speaker had helped them "no forrader." He regarded the cytoplasm as the fundamental part of the cell. Professor Keeble said that a savage who met a motor car and at once proceeded to explain its origin would be in a similar position to those explaining the synthetic life, but they were sillier than he. Professor MacAllum held with Tyndall that matter was endowed with the potentiality of life. The organism which was first formed was ultramicroscopic, perhaps under the two-hundredth of a micron. Prof. Benjamin Moore declared he still worshiped at the shrine of vitalism. He thought that life might still be originating. When the colloids got under sunlight they began synthetizing organic bodies and so the process continued. A picture consisted of the artist's soul as well as of pigment, so to those who could recognize, it there was a soul of living beings. Professor McCullam saw no hope of our ever being able to explain how life arose but would not dissuade others from searching. The alchemists who searched for the philosopher's stone founded chemistry and those who sought the elixir of life founded therapeutics. Dr. Haldane suggested that by analysis of the organic we might some day get down to the inorganic (chemically speaking) and then see that this was an organic world, so we must study atoms and molecules to lead to a notion of the origin of life. Dr. Chalmers Mitchell said that was mere verbal nonsense. What they called life was only the result of observations about human beings. To extend it to anything else was pure metaphysics. Rev. T. Stebbing revived the old story of an Oxford Don who said he had listened to university sermons for forty years and was yet a Christian, and thought some of the audience might go home and tell their friends they had heard learned speeches on the origin of life and had left with the firm conviction that life never had an origin at all.

Next year's meeting is to be held at Birmingham from the 10th to the 17th of September and Sir W. H. White has been chosen as president. In 1914 the meeting is to be in Australia. Invitations for the two following years have been received from Manchester and Newcastle.

A report by Dr. Franklin Parsons on the utility of isolation hospitals has been issued by the local government board as a supplement to their last year's report of their medical officer. The construction and design of these hospitals is considered and suggestions are made for reducing their cost. Dr. Parsons visited twenty-four of these existing hospitals and reports upon them. The board's medical officer introduces the report in a preparatory letter, describing it as containing information very valuable to sanitary authorties and their officers who may have to prepare plans for new isolation hospitals.

The death has occured of Dr. Reginald Thompson, aged 78. He was on the staff of the Consumption Hospital, Brompton, as acting and consulting physician for about 30 years. He was M. D. Cantab. 1863; was elected F. R. C. P. in 1868. He was appointed secretary of the Royal Medico-Chir. Society in 1880 and V. P. in 1883. He wrote "The Different Aspects of Family Phthisis" (1884) and contributed on various subjects connected with consumption to the societies and journals.

The death of Mr. L. A. Bidwell, senior surgeon to the West London Hospital, took place on Monday, September 2, at 4 o'clock. He took the M. R. C. S. in 1887 and the Fellowship in 1890. Besides other appointments, he was surgeon-major in the Royal Hussars Yeomanry. He wrote a "Handbook of Intestinal Surgery" in 1905 and had been a liberal contributor to societies and journals, particularly on points connected with the surgery of the abdomen.

Surgeon-General (retired) D. A. Campbell Fraser, M. O. Edin., died on the 28th ult., aged 80. He served in the army medical department about 40 years, and had held staff appointments at Malta and Netley. Had been Red Cross Commissioner in the Russo-Turkish War and received the medal for Ashanti, 1873-4. He also had the Roumanian Star.

Staff-Surgeon R. N. Charles Ede (retired) has died a nonagenarian. The latter part of his life was in private practice, contrasting strongly with his earlier career. Qualifying in 1844 he entered the navy the next year and first served in the Pacific zone four years, and then was appointed surgeon and naturalist to the *Assistance*, going to the Arctic region in search of Sir John Franklin. They found the winter quarters and débris of Franklin's expedition. Surgeon Ede was in sledge parties by which further traces were found, and returned to the ship with frost-bitten and snow-blind patients.

Progress of Medical Science.

Boston Medical and Surgical Journal.

1. Indications for the Major Obstetrical Operations F. S. Newell.
2. The Salvarsan-Calomel Treatment of Syphilis. W. F. Boos.
3. The Bacteriological Diagnosis, Intubation and Antitoxin Treatment of Diphtheria. E. H. Place.
4. The Significance of Symptoms in Pulmonary Tuberculosis. H. D. Chadwick and H. S. Wagner.

2. The Salvarsan-Calomel Treatment of Syphilis.—W. F. Boos believes that whether or not salvarsan alone is capable of curing syphilis is an open question. Its action is undoubtedly much more powerful and rapid than that of calomel, but perhaps it is not as enduring as calomel action. When an early and effective calomel treatment is used less salvarsan is necessary. In any event, a proper combination of the two drugs makes it possible to cure syphilis in one-sixth the time required when calomel alone is used; and the treatment is much milder. In secondary cases the author usually begins with a calomel treatment of 8 intramuscular injections: 2 of 70, 2 of 60, 2 of 50, and 2 of 40 milligrams. If the patient is afflicted with serious secondary symptoms such, for instance, as laryngeal syphilis with an intense and constant cough and almost complete loss of voice, he is immediately given two or three intravenous injections of salvarsan, three or four days apart, before the calomel treatment is begun. The injections of calomel are given every four to five days, and if the patient's condition allows he receives two more injections of 40 milligrams each when the first 8 are complete. The calomel makes the patients feel considerably prostrated in most cases, although some of them bear up remarkably well under the injections. During the calomel treatment the patient must take the very best care of himself; he should stop work if possible, he must go to bed immediately after each injection, and he must refrain from the use of alcohol for an indefinite period. It is noted that the intravenous injections of salvarsan, which follow the calomel after the lapse of a few days, quickly bring the patient back to a state of comparative well-being. The injections of salvarsan are made at intervals of from three to four days; and five or six injections are given in all. In ordinary cases men receive from 0.5 to 0.6 gram salvarsan at each treatment, while women are given somewhat less. The calomel must be given as a fine suspension in oil of sesame.

4. Significance of Symptoms in Pulmonary Tuberculosis.—H. D. Chadwick and H. S. Wagner emphasize the importance of watching for early subjective symptoms, as by them a diagnosis may be made before ulcerative processes occur to free the bacilli. The finding of bacilli depends much upon the persistence of the search made for them. Tuberculosis, even in advanced form, may be present without bacilli appearing in the sputum. In suspicious cases it is better to give patients the benefit of the doubt by telling them that their symptoms indicate early tuberculosis and that to prevent further progress it will require a radical change in their mode of living. If a patient is sent to a sanatorium with a doubtful diagnosis no harm will have resulted, even if the condition should prove to be a simple bronchitis or an influenza infection.

5. Diagnostic Aids in Gastric Diseases.—E. A. Aronson states that from study of the diagnosis of gastric diseases, both clinically and in the laboratory, he is compelled to admit that as yet there are no absolutely reliable diagnostic aids and that consequently much is left to be desired. Every case demands, in addition to a careful consideration of the subjective history, the application of every possible laboratory aid to the physical examination. It is still frequently a most difficult thing to make certain a differential diagnosis between a functional and an organic lesion. The positive diagnosis of an ulcer is not always easy, for even a hematemesis cannot be considered a cardinal symptom. No great ingenuity is required to diagnosticate a malignant growth if one can palpate a distinct tumor of the stomach and find all other signs and symptoms of malignancy. The early diagnosis of this disease, in the absence of such a mass, despite the most careful chemical study and the applicaion of all the known biological tests, remains the same difficult problem encountered by preceding generations of clinicians. The author is optimistic enough to believe that this difficulty will also be overcome in the future, and perhaps that one's greatest aid may lie in the further development of röntgenology

6. Trachoma.—H. M. Friedman notes that trachoma is a chronic, malignant, and highly infectious disease of the conjunctiva, attacking principally people living in crowded and unhygienic surroundings. It almost always commences in the palpebral margin of one of the upper lids; it is pathologically a diffuse subepithelial, white celled infiltration of the conjunctiva; its most serious complication is pannus; and a cure is effected by the replacement, in a characteristic manner, of the mucous membrane by scar tissue. The ideal treatment is any method which promotes scarring, with the extirpation of isolated areas which have finally refused to heal.

8. Mitral Stenosis and Pulmonary Tuberculosis.—W. Narins points out that mitral stenosis and pulmonary tuberculosis may occur in the same individual. This fact is now admitted by almost all authorities. Franke's statement that he never saw a case of tuberculosis following a mitral stenosis with well marked hypertrophy of the right ventricle is clearly only personal experience. In a series of positive cases of pulmonary tuberculosis treated at the author's tuberculosis clinic, there were sixty-two with cardiac complications of all sorts. There were twenty-five cases of mitral insufficiency. There were seven cases of mitral stenosis and one of mitral stenosis and insufficiency. The author concludes from his experience that the passive congestion of the lung due to the mitral stenosis acts in a favorable way on the tuberculous process in the lungs.

9. Heart Disease and Pulmonary Tuberculosis.—N. G. Seymour finds that one of the most frequent errors encountered in diagnosis is that of pulmonary tuberculosis in cases of uncomplicated chronic endocarditis; that the combination of these two conditions is not very unusual, and that therefore the recognition of an undoubted heart lesion does not preclude the possibility of a coexistent tuberculosis of the lung.

3. **Bacillary Dysentery.**—C. J. Hunt believes that while there is some warrant for the terms "dysentery" and "paradysentery," the more general one of "bacillary dysentery," insofar as preventive medicine is concerned, simplifies the problem both of diagnosis and of sanitary supervision. There is apparently a notable lack of recognition of the etiology and probably of the pathology of cases infected by members of the dysentery group, resulting in a longer continuance of the infecting source and a higher mortality; this is evidenced in the varied diagnoses such as "diarrhea," "winter cholera," "intestinal grip," "grip," "gastric fever," "intestinal disorder" and many others. Dependent on the casual association of the *B. typhosus,* outbreaks of bacillary dysentery may be followed within ten to twenty-one days by a marked increase in the number of typhoid fever cases. This occurred in five out of nine instances in Pennsylvania and may serve as a warning of the presence of the more serious infection; the immediate abatement of the sources would probably decrease the morbidity and mortality due to typhoid fever.

7. **Cultivation of Malarial Plasmodia.**—C. C. Bass reports that he has succeeded in cultivating the malarial plasmodia in human serum, in Locke's fluid (from which calcium chloride, is omitted) and in human ascitic fluid. In the majority of cases it was found that dextrose must be added to the medium in order to secure growth of the parasites. The plasmodia grow in a thin layer near the top of the cell sediment, beneath which zone the parasites all die. The parasites have been cultivated only in the red cells of human blood and are destroyed by the leucocytes as soon as they are liberated from the erythrocytes, and also by the serum, Locke's fluid, ascitic fluid, or, by any of the other media experimented with. Plasmodia develop readily in the red corpuscles, apparently digesting the substance of the corpuscles, and segmentation can be followed with great satisfaction in the cultures. The most favorable temperature found for the cultivation of these protozoa is about 40° C. They will usually live at a lower temperature, but often will not grow, and as a rule will not multiply. Positive cultures have been obtained from twenty-nine cases of estivoautumnal, six cases of tertian and one case of quartan malaria. The cultures have been carried on as far as four generations from the parent culture and with proper attention to technique can doubtless be maintained indefinitely. Only the asexual cycle of the parasite has been observed in the author's cultures.

10. **The Parathyroids and Infantile Tetany.**—C. G. Grulee states that there is no absolute evidence that lesions of the parathyroids are responsible for cases of infantile tetany. The removal of the parathyroids in adults and animals produces a condition which, if not identical, closely simulates spasmophilia. In a majority of cases of infantile tetany there is found some lesion of the parathyroid glands. There is strong reason to believe that the same disturbance of salt metabolism occurs in the tetany of animals produced by thyroidectomy as in the spasmophilia of infants. It is likely that lesions of the parathyroids are causal factors in infantile tetany, but that it has not been proved that such lesions must exist in all cases.

1. **Eye Symptoms in Nervous Diseases.**—J. Hinshelwood presents a number of examples showing the intimate connection which frequently exists between the eye symptoms and the diagnosis of diseases of the nervous system. He directs special attention to the fact that by careful and systematic observation of the eye symptoms in all cases of disease of the nervous system the physician is able in many cases to arrive at a diagnosis at a much earlier period than would be possible from consideration of the other symptoms alone.

2. **Septicemia with Local Endocardial Lesions.**—J. Henderson states that cases of infective or malignant endocarditis are now recognized to be really varieties of acute septicemia, often cryptogenetic, with localization on the endocardium, though the symptoms are not necessarily those of the local lesion. The condition is one which is undoubtedly much more frequent than the records show, as ofttimes there is no symptom or physical sign to suggest such a lesion. The more acute forms are most often recognized, but the more chronic types may only be recognized very late in the course of the disease, or may defy diagnosis to the end. Textbooks do not usually portray anything like a complete clinical picture of the disease—its mode of onset, its symptoms, and its course are so varied. The textbook classification recognizes various distinct types. Two special types are described, the typhoid and the septic, the former being the much more common. A third, and much less frequent type, is mentioned where the predominant symptoms are meningeal. In all these the cardiac symptoms are in the background. There is in addition a large group in which the cardiac features are pronounced, and often these prove to be the most chronic and most difficult to recognize as malignant. From a diagnostic point of view three cardinal signs may be recognized: (1) The presence of valvular disease as determined by cardiac examination; (2) the occurrence of embolism; and (3) the discovery of microorganisms in the blood stream. If these three signs occur together a confident diagnosis of infective endocarditis may, in the great majority of cases, be made, although often the diagnosis must be made on much more slender foundation.

4. **Acute Pancreatitis.**—W. Billington and B. G. Goodwin allude to the rarity of recovery from acute hemorrhagic pancreatitis and report two cases recently under treatment in the Queen's Hospital, Birmingham. In each case both sacs of the peritoneum were drained, appendicostomy was performed, and through the opening in the appendix large quantites of saline solution were introduced into the large bowel. The amount of fluid absorbed was surprising and the effect was most gratifying, a practically uneventful recovery following the operation in each instance.

5. **Chronic Edema of One Leg in a Child.**—E. O. Hughes records a case of this condition in a girl aged six years. It is classed provisionally at least, with those instances of non-congenital edema of the lower extremities in children, a fair number of which have by now been reported, and which resemble this one both in many of their clinical features, and in the absence of any known path-

ology—the title "trophedema" (Meige) being both vague and of doubtful warrant. A few of these cases have been unilateral. On the other hand, in the case of the author's patient the general character of the edema and its anatomical accuracy afford so complete a picture of obstruction of one external iliac vein that any other diagnosis could only be safely accepted if a direct exploration of the parts proved negative.

7. **The Care of Consumptives.**—T. G. Lyon concludes that no reliance can be placed on specific remedies. Sanatoria conducted on rational lines are essential in the treatment of those consumptives whose life-work is under the direction of others. Consumptives of humble means should be provided for by an extension of the present hospital system, aided by the State and supplemented by additional sanatoriums. The sanatorium treatment, owing to its slacking influence, is not fitted to patients in positions that require the display of initiative and entail responsibility. These patients are best treated apart from others, without isolation from their usual surroundings, and as far as possible in touch with their business.

1. The Nature, Origin, and Maintenance of Life. E. A. Schäfer.
2. The Influence of Muscular Exercise and Open Air on the Bodily Functions. L. Hill.

1. **The Nature and Origin of Life.**—By E. A. Schäfer. (See MEDICAL RECORD, September 28, 1912, page 582.)

2. **Influence of Muscular Exercise and the Open Air on the Bodily Functions.**—L. Hill concludes that all the efforts of the heating and ventilating engineer should be directed towards cooling the air in crowded places and cooling the bodies of the people by setting the air in motion by means of fans. In a crowded room the air confined between the bodies and clothes of the people is almost warmed up to body temperature and saturated with moisture, so that cooling of the body by radiation, convection, and evaporation becomes reduced to a minimum. The strain on the heat-regulating mechanism tells on the heart. The pulse is accelerated, the blood is sent in increased volume to the skin, and circulates there in far greater volume, while less goes through the viscera and brain. As the surface temperature rises, the cutaneous vessels dilate, the veins become filled, the arteries may become small in volume, and the blood pressure low, the heart is fatigued by the extra work thrown upon it. The influence of the heat stagnation is shown by the great acceleration of the pulse when work is done and the slower rate at which the pulse returns to its former rate on resting. The increased percentage of carbonic acid and diminution of oxygen which has been found to exist in badly ventilated churches, schools, theaters, and barracks, is such that it can have no effect upon the incidence of respiratory disease and higher death-rate, which statistical evidence has shown to exist among persons living in crowded and unventilated rooms. The conditions of temperature, moisture, and windless atmosphere in such places primarily diminishes the heat loss, and secondarily the heat production—that is, the activity of the occupants, together with the total volume of air breathed, the oxygen taken in, and the food eaten. The whole mechanism of the body is thus run at a lower plane, and the nervous system and tone of the body are unstimulated by the monotonous, warm, and motionless air. If hard work has to be done it is done under conditions of strain. The number of pathogenic organisms is increased in such places, and these two conditions run together—diminished immunity and increased mass influence of infecting bacteria. The bodily mechanisms become trained to maintain the body heat by habitual exposure to open-air life. The risk lies in overheating our dwellings and overclothing our bodies.

Berliner Klinische Wochenschrift.

September 2, 1912.

Vital Coloration and Chemotherapy.—Goldmann continues his labors in this field, as to which the profession is much confused. He wishes to set it right. A true vital stain must remain in the tissues for a long time; it must not be too toxic; it must be able to penetrate into the cell interior, etc. Substances which come up to these standards are trypan blue, isamin blue, and pynol blue. Vital stains are of two classes, one of which acts rapidly, the other slowly. Trypan blue belongs to the former, for it stains tissues *in vivo* within three hours. Isamin blue belongs to the second class. The more dilute the solution and the slower the absorption, the more marked is the histological picture. The distribution of the vital staining is highly suggestive. In a pregnant animal it is notably in evidence about the animal's dugs. But if an animal which is vitally stained conceives, then the external tissues become decolorized and the staining matter appears in the placenta. Further, if a disease focus is set up in a vitally stained animal it attracts the staining principle. What is the meaning of this displacement? The internal organs which naturally attract the stain are the kidneys. This we associate with an attempt at excretion. No other organ with excretory outlet tends to store up the coloring matter. The ductless glands take up the latter in a manner not haphazard, but characteristic for each. A complete survey of the tinctorial qualities of the various tissues appears to show that the cells which stain are essentially migratory, histogenetic, and phagocytic, and their tinctorial property is the result of a peculiar chemotactic sensitiveness. We can therefore comprehend why the breasts of the gravid animal and the placenta attract the coloring matter because cells of this type naturally abound in such organs which also tend to store up glycogen and fat. The embryo is not stained, so that one may also regard the storing up of the stain by the placenta as protective. In the presence of the new physiological and pathological aspects of vital staining the pharmacological significance must recede for the time being. The latter is chiefly concerned with the utilization of the vital stain as a vehicle for some specific substance able to destroy pathogenic cells, bacteria, etc.

New Development in the Serotherapy of Pneumonia.—Géronne writes optimistically of a new phase in the use of antipneumococcus serum in pneumonia. At Wiesbaden the mortality has been running over 30 per cent., many deaths occurring a week or ten days after the crisis, while disastrous complications were common. Treatment seemed almost valueless. The national resource appeared to be early intravenous injection of a serum, but the author hesitated to use the one ordinarily available. A new preparation made by the local serum institute specially devised for intravenous exhibition was then introduced in routine application as soon as the diagnosis was established. The dosage was high for the purpose—20 c.c. at least for initial dose, doubled in severe cases, and repeated daily when benefit was not apparent. A successful serum should be able to modify favorably and promptly the course of the disease, and this occurred in almost all of the series. In some a shortening of the course and premature crisis was apparent. The local disease process did not appear to be affected, and it is even not impossible that resolution of the exudate may be retarded. In the two cases which seemed most conclusively aborted the patients continued to have rusty sputum for a number of days. A specific therapy entails its own drawbacks. When bacteria are killed their toxins are set free, when tumor cells are destroyed they give rise to sapremia, and when a toxemia is neutralized the local lesions may show aggravation.

Münchener medizinische Wochenschrift.

September 3, 1912.

Acute Blindness from Drug Poisons.—Harnack considers this subject with chief emphasis upon methyl alcohol blindness. One type of blindness, due to such dissimilar drugs as methyl alcohol, nitrous acid, and atoxyl, comes about because of the action of activated oxygen on the nervous elements of the eye. The process which causes blindness is an acute inflammatory-degenerative one attacking the said elements. Of other poisons able to destroy vision—quinine, cocaine, and filix mas—the mechanism is entirely dissimilar in that there is produced a violent spasm of the retinal vessels which has the same result as an embolus of the central artery. The obstructed vascular area perishes and the nerve elements undergo atrophy.

Familial Occurrence of Facial Paralysis.—Weber refers to a recently reported episode in which facial paralysis was known to have occurred in grandmother, mother, and child. A few other cases of this familial incidence were already upon record. To this material the author adds another family affected with so-called rheumatic facial paralysis. The first patient seen was a girl aged nine years who had waked in the morning with a right-sided lesion. All the branches of the facial were involved. There were no collateral phenomena, nor was there anything to explain the case. There was spontaneous recovery in about three weeks. The author had already treated two sisters, the patient's aunts, for the same affection, the mother and grandmother having been free from attacks. The cases of the aunts were similar throughout to that of the patient. Only in one case there were symptoms suggesting an aural reflex. This case was also more severe and protracted, and is the only one in which a second attack has thus far occurred. There were thus four cases in the same family. The limitation to one sex is characteristic of much familial incidence of disease.

Biological Diagnosis of Pregnancy.—Abderhalden continues his work upon this new resource. The technique is still very complicated and the method requires familiarity to give results. The reaction itself is sharp and unmistakable. Controls, however, are of great use when there is a possibility that the test materials have become too old for employment. The reaction is based on the fact that homogeneous albumin, which is, however, alien in the blood, is decomposed by the enzymes of the latter. Several tests may be employed. In one the blood serum or plasma of a granula when mixed with placenta albumin or peptone will alter the composition of the latter, as shown by the polariscope. Since this test might exceptionally fail the method of dialysis will serve as a check. A special polarizing tube and dialyzing apparatus are employed. When properly carried out pregnancy may be diagnosticated by the first month, and not only human pregnancy, but gestation in all animals thus far tested. Not only normal, but tubal, pregnancy, vasicular mole, and retained placenta have been recognized. The full details of the technique, as in all biological reactions, are too long for recapitulation.

Deutsche medizinische Wochenschrift.

September 5, 1912.

Artificial Impregnation in Epididymitis Duplex.—Rohleder, the authority on artificial impregnation, considers this very important phase of the subject. Many a great estate has had no direct inheritor because the owner had been sterilized by an early gonorrhea. Fortunately, double epididymitis is rare. Two or more problems arise in this connection. One is the possibility of a plastic restoration of the lumen of the epididymis. This has been effected in a few cases, perhaps. If the case is seen early enough it may be possible to cause absorption of the exudate and thus restore the lumen. The rest of the alternative consists in obtaining semen from the testicle, the latter being intact, and practising artificial impregnation. This latter course does not necessarily exclude attempts to restore the patency of the ducts. The author reminds us that with double epididymitis there is usually prostatitis, so that restoration of the lumen need not mean patency; and if healthy prostatic fluid is necessary for the activity of the spermatozoids artificial impregnation with the direct product of the testicle could fail, more especially because the passivity of the female in the act is accompanied by failure of cervical mucus, a second element in activating the sperm. These considerations, however, are largely theoretical. The author suggests that experiments be made with cases not over two years old; that the semen be first examined under the microscope; that the patient's prostatic fluid obtained by stripping also be examined. If the latter is healthy an ejaculate could be obtained by intercourse with a condom. This might be added to the semen under certain conditions. It is also possible to treat a diseased prostrate until the ejaculate becomes normal. The author professes doubts that a successful impregnation of any sort has occurred after double epididymitis. We only know that living semen can be obtained by testicular puncture, but in too slight amount to be injected into the uterus without dilution. The latter must guarantee that the spermatozoids will keep active until they can reach the ovum, not a simple matter under the most favorable conditions. The proper vehicle should be healthy prostatic fluid.

Physical Therapy of Psoriasis.—Axmann lauds non-pharmaceutical procedures for the management of psoriasis. Even malignant diseases show a higher percentage of actual recoveries than this benign affection, of which it is to be doubted if a single radically cured case has ever been seen. The author some time ago reported the use of carbonic acid snow to destroy permanent foci. He also uses *x*-rays and the uviol lamp on obstinate lesions. For recent small lesions he now recommends the use of cold, ice being applied for from fifteen to thirty seconds. It is thus possible to treat the entire back in one session. The ice is applied by a special device. Patients actually prefer the discomfort of the cold to that of grease, with its staining of underwear and bedding. This management should consort well with the dietetic-hygienic treatment.

Diabetes and Pregnancy.—Bingel states that but eighty cases are upon record in which pregnancy has accompanied true diabetes—a remarkable fact when we consider the frequent association of gestation with simple glycosuria. That failure of conception is due to diminished libido sexualis is difficult to believe because anaphrodisia is common enough in women who conceive readily. A more probable reason is a diabetic atrophy of the genital structures sometimes known to occur, or endometritis, which is common in diabetics. About one-third of the diabetic pregnancies have resulted in abortion. In some cases the women were healthy at conception, developing acute diabetes afterwards, but as a rule diabetes preceded conception. Gestation does not aggravate diabetes sufficiently to justify therapeutic abortion.

Spirocheta Phagedenis—A New Species.—H. Noguchi has succeeded in isolating a hitherto undescribed spiral organism in pure culture from a case of mild phagedenic ulcer on the external genitalia of a woman. For this organism the name *Spirocheta phagedenis* is proposed. *Spirocheta phagedenis* is a strict anaerobe and grows in the presence of fresh tissue in ascitic agar. It produces no apparent change in the media, but a somewhat offensive odor develops in the culture tube. *Spirocheta phagedenis* incites a slight inflammatory reaction in the skin of a *Macacus rhesus* monkey and in the skin and testicles of rabbits. Its etiological relationship to the phagedenic lesions on the external genitalia has not yet been determined.—*Journal of Experimental Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE URINE.

Tests for Sugar.—If there is much albumin in the urine, it should be removed before testing for sugar, as it may interfere with the reaction. This may be done by rendering the urine faintly acid by the addition of two or three drops of acetic acid and boiling. Then filter the specimen to remove the coagulated albumin. The urine is then ready for the sugar test.

The urine must be fresh, as a small amount of sugar might be lost by decomposition.

The best reduction tests for the examiner in the field are those in which the salts of copper and bismuth are used, but as other substances besides sugar possess the power of reducing copper and bismuth salts, the reduction tests are only of negative value. The absence of reaction, then, indicates the absence of sugar, but the presence of a reaction simply shows that some reducing agent, probably sugar, is present.

In order to determine whether or not the reducing agent is sugar, the examiner must resort to the fermentation test, this being the only reliable positive test. The phenyldrazine test is no longer regarded as positive, as it has been discovered that the characteristic crystals may form through the influence of other substances besides sugar. Furthermore, the characteristic crystals are sometimes not produced even when sugar is present.

Fehling's Test. The two solutions should be kept separately in well-stoppered bottles in the dark. When the reagent is wanted, equal quantities should be taken from each bottle and well mixed. The resulting liquid is a transparent dark blue. One dram of this should be put in a test-tube and gently boiled. Then urine should be added, a few drops at a time, and the boiling continued. If sugar be present, the solution assumes an opaque color, and soon a dense, yellowish red sediment falls to the bottom. Should no change occur, urine must be slowly added until its volume equals but does not exceed that of the reagent. After the urine is added, boiling should not continue more than half a minute, for the reaction is prompt. Simple discoloration of the reagent does not indicate sugar, nor does the formation of a grayish cloud which is due to the precipitation of earthy phosphates.

Haine's Test. The formula for this solution was devised for the purpose of furnishing a reagent that is not liable to spontaneous decomposition. Late experience, however, has demonstrated that it will not always keep indefinitely as was formerly supposed, and that it is important for the examiner to observe, after boiling the test solution and before adding the urine, whether or not any of the copper salt has been reduced. If the solution remains clear on boiling, it has not deteriorated.

In testing with this solution put about 1 dram in a test-tube and gently boil. Then add the suspected urine, drop by drop, up to eight drops—not more—while continuing to boil. The same reaction occurs as with Fehling's solution. If much sugar is present it will show with the first drop or two, but in no case should more than eight drops of urine be added.

Nylander's Test. This is the best solution in which bismuth is used as a reagent. It is a modification of Boettger's test and consists of two grams (30 grains) of bismuth subnitrate and four grams (1 dram) of Rochelle salt (potassium sodium tartarate) dissolved by the aid of gentle heat in 100 c.c. (26½ fluid drams) of a 10 per cent. solution of sodium hydrate. It has the advantage over Fehling's and Haine's solutions of not spoiling and it is not so readily reduced, being unaffected by chloral, pyrocatechin or glycosuric acid. It is, however, less delicate than Fehling's, detecting only 1/10 per cent. of glucose and that imperfectly, but that is good enough for all clinical work. The most delicate method of applying the test is to fill a test tube about half full of urine and then add about one-third as much of the reagent, mixing them well together. Boil the upper portion, and if sugar is present a dark brown or black precipitate of metallic bismuth and bismuth suboxide is produced. Boiling should be maintained for one minute if necessary. The formation of a light-gray cloud is not significant, as it is simply due to earthy phosphates.

Fermentation. When one of the reduction tests previously described fails to show the presence of sugar, the result may be regarded as final and no corroborative test is called for. If, on the other hand, a reaction is obtained with any one of them, the strong probabilities are that it is due to sugar and the examiner must assume this to be the case until he proves by means of the fermentation test that no sugar is present and that the reaction was due consequently to some other agent. In this test the sugar present in the urine is fermented by the aid of ordinary yeast and the carbon dioxide given off is collected and measured. As fermentation proceeds, the gas collects in the upper part of an inverted tube, driving out the urine. The simplest and best way of applying the fermentation test is by means of Einhorn's saccharometer. The following precautions must be observed:

(a) The temperature should preferably be between 80° and 90° F.

(b) While fermentation is going on, the temperature must never rise above 115° F., for yeast cells are killed at that point.

(c) The temperature should not be constantly below 60°, for fermentation proceeds very slowly or not at all below this point.

(d) In every case a control test should be made. This should be done with a normal urine, known not to contain sugar. This control is of great value, for as all yeast contains a little glucose, the presence of a bubble of gas at the top of each tube shows the yeast is fermenting properly, and at the same time the examiner can see whether or not more gas is forming in the suspected urine.

(e) In a doubtful case at least twenty-four hours should elapse before declaring that the test gives no reaction.

(f) The urine must be free from antiseptics or preservatives.

Proposed Changes in Workmen's Compensation Act.—Recently the Washington State Medical Society went on record as the result of a conference with members of the industrial insurance commission, prominent employers, and others as favoring the following changes in the existing workmen's compensation act: The establishment of a first aid fund; removal of the $10 fee limit for expert testimony, establishment of a minimum charge of $5 for special examinations of injured workmen, and of a fee of $2.50 for accident reports, to be paid for by the taxpayers.

Book Reviews.

Direct Laryngoscopy, Bronchoscopy, and Œsophagoscopy. By Dr. W. Brünings. Translated and Edited by W. G. Howarth, M.A., M.B., B.C. (Camb.). F.R.C.S. (Eng.). Pp. v-370. Price $5.00. New York: William Wood & Co., 1912.

Mr. Howarth has rendered a very distinct service to the profession in translating this excellent work, and is to be congratulated on the result of his effort. It can be fairly said that Brünings' untiring zeal in perfecting his direct instruments and technique has served to make known the details of this highly specialized work throughout the civilized world. Thoroughness is one of the most insistent qualities of this famous teacher, and therefore in this work not a detail has been overlooked, so that even the unpractised physician who is confronted by his first foreign body patient may, after a careful study of this volume, approach the case with a feeling of assurance. There are chapters on local and general anesthesia with the complications that may arise therefrom, on the mistakes and difficulties one encounters, on the manipulation and care of instruments, on endoscopy in children, and on esophagoscopy. The book contains many excellent plates and figures and is the most comprehensive treatise of its kind which has as yet been published.

Vorlesungen über Diätbehandlung innerer Krankheiten. Gehalten vor reiferen Studierenden und Ärzten. Von Prof. Dr. H. Strauss, Direktor der inneren Abteilung des jüdischen Krankenhauses in Berlin. Mit einem Anhang "Winka für die diätetische Küche" von Elise Hannemann. Vorsteherin des Haushaltungs-Lehrerinnen Seminars und der Kochschule des Lette-Vereins in Berlin. Dritte, vermehrte und verbesserte Auflage. Price 8.60 marks. Berlin: Verlag von S. Karger, 1912.

Three editions of this book have appeared within four years, which amply indicates the increasing circle of those who would profit by the valuable course of lectures on dietetics given by Prof Strauss in Berlin. These lectures are, however, presented in a more elaborate form than originally delivered, and after each one there is appended a comprehensive bibliography. The present edition contains many additions and revisions that have been demanded by recent research; this is particularly apparent in the sections dealing with gastric ulcer, heart disease, diseases of the kidney, gout, and diabetes. A new chapter on the dietetics of old age has been added. One of the important features of this volume is the comprehensive list of tables giving the chemical composition of the various nutrients and accessory articles of food both in the raw and in the prepared state. The section on "hints for the diet kitchen" contains a large number of valuable recipes in addition to the clear instructions regarding the preparation of food for the sick.

On Bronchial Asthma, its Pathology and Treatment. By J. B. Berkart, M.D., late physician in the City of London Hospital for Diseases of the Chest; Corresponding Member of the Societé Royale des Sciences Médicales et Naturelles de Bruxelles, of the Physikalish Medizinisch gesellschaft of Würzburg, of the Société de Médecine de Paris, etc. Revised and abridged, third edition. Price, $2.00 net. London, Edinburgh, New York, Toronto and Melbourne: Henry Frowde, Oxford University Press, 1911.

The present edition of this well-known work represents not only a revision, but also an abridgment of the former edition. The latter change has been effected by a discussion of only the most important practical points pertaining to the subject and the omission of needless theoretical discussions. The author deals in turn with a review of the current pathology, and with the clinical history, the pathological anatomy, the nature and causes of the dyspneal paroxysms, the diagnosis, and the treatment. His theory of the causes of asthma is mainly as follows: The dyspnea is a symptom of, or an accident connected with, some form or forms of bronchial catarrh of chronic nature. The dyspneal paroxysms are seen only in individuals in whom the general nutrition is more or less impaired. When the accumulated catarrhal products form an impediment sufficiently great, an intense dyspnea ensues, and lasts until the obstacle is for the time removed and expectorated. One of the measures that the author has found to be successful in the treatment of cases in which other and orthodox methods of removing the obstruction have failed, has been the injection of diphtheria antitoxin. In some unknown manner this has a solvent action upon the fibrinous exudation. Among the many other measures, dietetic, climatic, hygienic, and medicinal, which the author discusses in detail is the employment of frequent hot baths. He finds no contraindications to the use of morphine for meeting the pressing needs of the moment. Anyone who has ever treated a case of asthma, and no practitioner has ever been spared this duty, will find Dr. Berkart's volume a most illuminating and interesting one.

Manual of Surgery. By Alexis Thomson, F.R.C.S., Ed., Professor of Surgery, University of Edinburgh, Surgeon Edinburgh Royal Infirmary, and Alexander Miles, F.R.C.S. Ed., Surgeon Edinburgh Infirmary. Volume Second. Regional Surgery. Fourth Edition, Revised and Enlarged. With 274 Illustrations. Price $3.50. Edinburgh, Glasgow and London: Henry Frowde and Hodder & Stoughton, 1912.

The second volume of the series deals with regional surgery and is as complete a manual of the branch of surgery as could be included in a volume of the size presented. The descriptions of the conditions given in this book of some 900 pages are models of terseness, while at the same time enough is said to afford the medical practitioner or student ample opportunity for gaining a good insight into most methods of surgical treatment. The illustrations are numerous and good.

The Care of the Insane and Hospital Management. By Charles Whitney Page, M.D., Assistant Physician, Hartford Retreat, Hartford, Connecticut, 1871 to 1872 and 1873 to 1888; Superintendent Connecticut Hospital for the Insane, Middletown, 1898 to 1901; Superintendent Danvers State Hospital, Danvers, Massachusetts 1888 to 1898 and 1903 to 1910. Member of the American Medico-Psychological Association, the Boston Society of Psychiatry and Neurology, the New England Psychiatric Society, the Massachusetts Medical Society. Price $1. Boston: W. M. Leonard, 1912.

The writer in his preface styles his book a manual from which a "working knowledge of the best insane hospital methods and possibilities" may be obtained, and from which those interested can qualify themselves for official hospital duties or as philanthropists in the "neglected field" of public administration of the insane. Much of his effort of late years, he states, has been given to the practical elaboration of methods employed by Dr. Conolly, superintendent of the Hanwell Asylum, England, many years ago. Conolly was one of the pioneers of "non-restraint" and non-coercion in the care and treatment of the insane; and the book is to a considerable extent a statement of the internal workings of institutions where "non-restraint" is the practice. The writer does not hesitate to express views in which he will have the cordial sympathy of many asylum superintendents. A hospital with one head and a friendly board of trustees unhampered by politics; the superintendent to combine medcial knowledge with business ability, and a passion for justice; and a competent medical staff, acquainted with up-to-date methods, are some of the features insisted upon. There are chapters on the management of patients and on the nursing staff; and an appendix illustrating the management of a case without "restraint," and the importance of the card index in hospitals. The book is a simple and direct statement of some of the problems of management of hospitals for the insane by one who has had thirty-five years of experience as a medical officer and who would therefore seem to be a competent authority. We commend it to those interested as in line with other good books on the same subject.

Clinical Disorders of the Heart Beat. A Handbook for Practitioners and Students. By Thomas Lewis, M.D., D.Sc., M.R.C.P., Lecturer in Cardiac Pathology, University College Hospital Medical School, Physician to Out-Patients, City of London Hospital for Diseases of the Chest. Price $2.00. New York; Paul B. Hoeber, 1912.

In this book Dr. Lewis has had the happy idea of amplifying the new knowledge of the mechanism of the heart beat and the methods by which it is gathered for the benefit of the general practitioner, giving only such of the new facts and conclusions, and treating of such of the new methods as are of service at the bedside. The several subjects treated of in the seven chapters of the book are: The Recognition and Identification of Disorders of the Cardiac Mechanism; Sinus Irregularities; Heart-Block; Premature Contractions; Paroxysmal Tachycardia; Auricular Fibrillation; Alternation of the Pulse. The book is one of the most valuable of recent contributions to the modern science of the heart and its irregularities.

Fatigue and Efficiency. A Study in Industry. By Josephine Goldmark, Publication Secretary National Consumers' League. Introduction. By Frederic S. Lee, Ph.D. Containing also the substance of four briefs in defense of women's labor laws by Louis D. Brandeis and Josephine Goldmark. Price $3.50. New York: Charities Publication Committee, 1912.

The purpose of this book, which is one of the latest publications of the Russell Sage Foundation, is to show that apart from its humanitarian aspects the shortening of the hours of labor actually conduces to heightening the efficiency and improving the products of industry. The physiological basis of fatigue is carefully analyzed and its manifestations in the various occupations are reviewed in detail. The author displays a sympathetic grasp of her subject and imparts her knowledge with unusual perspicacity of style. The subject matter is divided into two parts. Part I contains the following chapters: Introductory; The Nature of Fatigue; The New Strain in Industry; Some Specific Studies of Physical Overstrain in Industry; Economic Aspect of Regulation: Fatigue and Output; Regularity of Employment; Fatigue and Overtime Work; The New Science of Management: Its Relation to Human Energies; The Enforcement of Labor Laws; Labor Laws and the Courts; Prohibition of Women's Night Work: A Prime Necessity; Conclusion.

Part II summarizes the world's experience upon which legislation limiting the hours of labor for women is based. One cannot better characterize this volume than by quoting the following appreciation from *The Survey:* "It affords a powerful argument for the most advanced position yet taken by the Federal Supreme Court with respect to governmental control over health conditions in industry. The book represents several years' work by one of the officers of the National Consumers' League. Its aim is to present, as a new basis for labor legislation, the results of the modern study of fatigue. It seeks to show what fatigue is, its nature and effects, and to explain the phenomena of overwork in working people. It draws upon the scientific study of fatigue—one of the most modern inquiries of physiological, chemical, and psychological science—for aid in the practical problem of reduing the long working day in industry."

Kidney Diseases. By W. P. Herringham, M.D., F.R.C.P., Physician to St. Bartholomew's Hospital, etc., etc. With chapters on Renal Diseases in Pregnancy by Herbert Williamson, M.D., F.R.C.P., Assistant Physician-Accoucheur to St. Bartholomew's Hospital, etc., etc. Price $5.50. London: Henry Frowde; Hodder & Stoughton, 1912.

It is a great pleasure to review a medical book in which both the scientific and the clinical aspects of a subject are so happily blended as is the case with the present volume. In addition, the reader's satisfaction is greatly increased by the author's facility of expression and command of an admirable literary style, which makes the work a very desirable addition to the excellent series of Oxford Medical Publications. As the title indicates, the scope of the book is very extensive and the whole range of renal affections, both medical and surgical, comes under consideration. The preliminary chapters dealing largely with the methods of diagnosis, the normal and abnormal constituents of the urine, etc., necessarily include a good deal of matter relative to laboratory procedures which in all cases, though, of course, not exhaustive, is thoroughly sound and reliable. The emphasis laid by the author on the desirability of invariably resorting to several tests when examining the urine for albumin is highly commendable in view of the frequency with which errors in diagnosis result from neglect of this simple precaution. In a later edition the phenolsulphonephthalien test will no doubt be inserted among the methods for determining renal efficiency in place of the complicated and little used procedure of Wright. Very interesting and thoroughly modern chapters are those on hematuria, family hematuria, and paroxysmal and other forms of hemoglobinuria. Edema is also well discussed, and though it might be said that the chapter on uremia is the least satisfactory one in the book it might also be said with equal truth that this is a subject on which it is at present impossible to write a chapter that is satisfactory. As is to be expected, in the chapters on nephritis, the clinician comes strongly to the fore, and in addition to adequate discussions of the pathological lesions well illustrated by case histories and microphotographs we find ample and very instructive directions in regard to the therapeutic and general management of the different forms and phases of the disease. Four chapters on renal disease in pregnancy dependent upon toxemia, pregnancy and chronic nephritis, hematuria in pregnancy, and pyelitis and pyelonephritis in pregnancy are from the pen of Dr. Herbert Williamson, and well deserve the graceful tribute paid them by the senior author in the preface. The latter third of the book is devoted largely to the suppurative renal disorders, hydronephrosis, new growths, calculi, syphilis, tuberculosis, etc., and evidently embodies the results of an unusually wide and intelligent clinical experience. The volume may be most warmly commended as a thoroughly recent and unusually satisfactory treatise on the highly complicated subject of renal disorders.

Sewage Disposal. By George W. Fuller, Consulting Engineer and Sanitary Expert, Member of the American Society of Civil Engineers, the American Institute of Consulting Engineers, the American Society of Mechanical Engineers, the American Chemical Society, the Society of American Bacteriologists, the American Public Health Association, etc. Price $6.00. New York and London: McGraw-Hill Book Company, 1912.

This book is designed to be a guide to both the practical sanitarian and the student of the ever-pressing problems of sewage disposal. No other problem of municipal development is at present so perplexing as this one, which, like that of the efficient ventilation of buildings, has led to endless discussion and controversy, not to mention the promulgation of a variety of more or less impractical or unsatisfactory schemes for the relief of conditions which are growing daily more intolerable and dangerous. Not the public alone but health officials and sanitarians generally are demanding more light upon this complex subject.

To all of these Mr. Fuller's book affords real and substantial aid. In it the problems to be solved are clearly stated, and each statement is followed by an exhaustive and impartial review of the steps that have already been taken in the solution of the question. In doing this the author draws upon a wide personal experience in practical sanitation, extending over a score of years, and he is almost too careful to give due credit to all of his predecessors and collaborators in this work. His attitude of mind is judicial and free from prejudice; while he saves himself from becoming too academic by drawing a practical conclusion from every phase of the subject which he discusses. He insists that sentiment should be banished and that the end ought in each case be echieved in the most economical manner, both as regards expense and efficiency. He prefers the Imhoff tank, as the best means yet devised for the sedimentation of sewage, but points out its possible defects.

Enzymes. By Otto Cohnheim, A.O. Professor of Physiology, Heidelberg. Six Lectures Delivered under the Herter Lectureship Foundation at the University and Bellevue Hospital Medical College. First Edition, First Thousand. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1912.

Although the text of this volume is composed of the lectures delivered at the University and Bellevue Hospital Medical College in this city under the Herter Foundation in 1910, the matter has been arranged in chapter form, so that all suggestion of discontinuity has been removed. The whole subject of enzymology is discussed in all its bearings, but in general terms so as to be appropriate for the needs of the average reader. The methods for the preparation, purification, and investigation of enzymes are described in the light of modern conceptions, but not in sufficient detail to make the book a guide for the worker in this field. Cohnheim's own views, of course, are given full expression and one finds in very succinct and readable form the results of the years he has devoted to the study of these mysterious agencies. The subject is one to interest every medical reader, and clinicians as well as laboratory men will derive much of value from the book. For example it is interesting to see that chymosin or the lab ferment of the older writers is not given a place in the list of eighteen ferments which Cohnhein says occur in the alimentary canal, his standpoint being that the clotting of milk which takes place in the stomach is not due to a special enzyme but is only an intermediate step in the process of peptic digestion. This conception means of course that a vast amount of work done by Hammarsten and his followers must be set aside, but it considerably simplifies the views as to the digestion of the proteids. This is only an instance of the progress that is being made in this fundamental study, and it goes without saying that the present volume forms an excellent résumé of the latest advances.

Society Reports.

AMERICAN ORTHOPEDIC ASSOCIATION.

Twenty-sixth Annual Meeting, Held at Atlantic City, N. J., May 30 and 31 and June 1, 1912.

THE PRESIDENT, DR. VIRGIL P. GIBNEY OF NEW YORK, IN THE CHAIR.

Suggestions for the Second Quarter of the Century.—Dr. VIRGIL P. GIBNEY of New York said that special attention should be called to the many diseases and deformities that had not been relieved by orthopedic measures. He mentioned, as instances in which perfect cures had not been secured, hip disease, Pott's disease of the spine, the spastic contraction in Little's disease, the more obstinate forms of rotary lateral curvature of osseous origin, and poliomyelitis, with its resulting deformities and disabilities.

An Anatomical Study of Many of the Cases of Lame or Weak Back, as Well as Many of the Leg Paralyses.—Dr. JOEL E. GOLDTHWAIT of Boston remarked that the lumbosacral, the lumbosacral transverse, and the sacroiliac joints bore a certain relation to each other in the production of a strain; and that the anatomical position of the lumbosacral cord and the spinal nerve roots with reference to the articular and transverse processes was an explanation of leg pain and paralyses.

Dr. J. T. RUGH of Philadelphia wanted to know whether there was anything in the previous histories of the cases to show that they presented the group of symptoms that Dr. Goldthwait had outlined.

Dr. C. L. STARR of Toronto asked whether there were not a series of the cases which gave absolutely no symptoms.

Dr. JOHN DUNLOP of Washington, D. C., had had a patient presenting a lumbosacral ossification on one side. There was no sign of a joint present, and the symptoms had come on after a slight accident on the opposite side from this bony ankylosis.

Dr. Z. B. ADAMS of Boston had found, in some patients suggesting the presence of stone in the kidney or ureter, a broad transverse process, which probably impinged on either the sacrum or the ilium of that side.

Dr. COMPTON REILLY of Baltimore asked whether there were ever any marked symptoms of nausea in these cases. He had had a patient who showed an *x*-ray in which the transverse process was shown to articulate with the sacrum and the iliac bone on that side. Some of her symptoms were marked pain at the menstrual periods, nausea for a long time, and pain in her back and limbs.

Dr. P. W. NATHAN of New York City considered the spine to be the most variable organ in the body, it being really a transition organ, particularly in its lower portions. He asked whether Dr. Goldthwait could demonstrate that these anomalies were not pathological, but merely subject to pathological conditions. He thought that lesions compressing nerves in this region would give distinct neurological symptoms, which could be definitely diagnosed.

Dr. JOHN DUNLOP of Washington, D. C., had noticed in the radiographs that the spine, in relation to the pelvis, did not seem to be symmetrical. He asked what effect that would have on the studies with respect to the crest of the ilium and the top of the sacrum.

Dr. S. M. CONE of Baltimore mentioned the case of a patient with a temperature of 103° and pain localized in the sacroiliac joint on one side. The *x*-ray showed an ossification on one side. He ordered a Wassermann test and a test for tuberculosis. It was a question whether it was ordinary infectious osteomyelitis. He wished to know whether any acute infection, syphilis or tuberculosis, could be an interpretation of some of these cases. The temperature had continued for a week. He thought it, of course, possible that spinal affection was at the base of the trouble.

Dr. A. H. FREIBERG of Cincinnati mentioned the case of a young woman, who had been referred to him because of an intense sciatica, associated with a decided asymmetrical position of the back. She had been pronounced to have all sorts of diseases. A careful *x*-ray plate showed a lumbosacral transverse process, and it appeared to him that a bone overgrowth was probably responsible for the pain. He undertook the removal of the bony process, which he found a very difficult operation; but it succeeded in relieving the patient completely. He asked whether there was a mechanical method of handling such patients, which would render such an operation as he had performed unnecessary.

Dr. H. P. GALLOWAY of Winnipeg, Can., wished to put on record a case similar to Dr. Freiberg's. The patient had suffered from mild sciatica for a number of years. The *x*-ray showed a spur on the transverse process, and Dr. Galloway recommended removal. There were no symptoms of sciatica after the operation.

Dr. GOLDTHWAIT, replying, stated that the specimens had all been taken from bodies that he had dissected. The *x*-rays were from his own clinic, and he could give the histories of them. He considered paraplegia a thing that must be reckoned with. In reply to Dr. Nathan, Dr. Goldthwait stated that the specimens he had shown were not simply the cauda equina, but were the roots that made up the different plexuses. In reply to Dr. Starr's question, Dr. Goldthwait said that he himself had not known that he had a peculiar formation of the transverse process of his last lumbar vertebra until the previous winter. With regard to treatment, he said that, recognizing these symptoms as being due to acquired conditions on top of a congenital malformation, the problem was to restore the condition to what it would be normally or was in early life. The individual should be balanced, so as to relieve the process of strain and irritation. If the pressure was all on one side and was distorting the spine, the patients could be relieved much less frequently than he had at first supposed. Not only were the nerves low down at the lumbosacral joint pressed upon, but the settling down of the processes might produce a pressure also on the nerves in the upper part of the lumbar spine. Dr. Goldthwait could not answer Dr. Reilly's question as to whether the condition would cause nausea. In reply to Dr. Nathan's second question Dr. Goldthwait said that it was for the members to decide whether the anomalies were of pathological importance. All he had claimed was that they were there. He thought that the lumbosacral joint would be subject to all the diseases to which any other joint was subject.

Spontaneous Gangrene and Allied Conditions in Orthopedic Surgery.—Dr. W. G. STERN of Cleveland stated that spontaneous gangrene, Raynaud's disease, erythromelalgia, acrocyanosis, and intermittent claudication were allied conditions, and were probably due to similar causes. Of fourteen cases that he reported, only five had been seen by the general surgeon; and then, only late in the disease, after gangrene had set in, for the purpose of amputation. Three of these cases had been transferred by the orthopedist to the general surgical service. Ten of the fourteen cases had been referred to the orthopedist early in the progress of the disease, on account of pain and discomfort in the feet and legs upon walking—most of them, under the impression that the condition was due to flat-foot. Seven cases had some degree of flat-foot, and several had been treated for the same with plates and exercises. One case had been held to be a sarcoma of the tarsus, while another had been suspected of being a tuberculosis of the ankle joint.

Dr. L. W. ELY of Denver spoke of the value of rest, and said that many years ago he had had a case in an adult, who had lost one foot by amputation for gangrene, beginning above the toe, and running to just above the knee. The other leg presented a well-marked case of intermittent claudication. The pulse was absent. It ceased about the middle of the leg. The patient had a well-marked phlebitis, and treatment was without effect. He was put on the flat of his back for six or eight months, and his symptoms all disappeared. Without rest he would have lost that limb also.

Dr. H. A. WILSON of Philadelphia asked Dr. Stern whether any of the cases had given a history of an onset after frost bite, with an exaggeration of the condition in the winter, and an amelioration in the summer. Dr. Wilson stated that such patients were relieved by applied warmth and complete rest. The circulation recovered, the gangrene disappeared, and there was an arrest in the condition, with a slight recurrence the following winter.

Dr. C. F. PAINTER of Boston remarked that until he had learned to associate etiologically with this condition the presence of various toxic conditions connected with narcosis, he had not understood the causation of these cases very well. There seemed to be two points connected with them: the fact that they occurred largely in persons that were fundamentally of a weak and unstable nervous system; and that they were found in those that gave a history of having used tobacco or some other toxic material to excess.

Treatment of Structural Scoliosis.—Dr. A. H. FREIBERG of Cincinnati stated that correction jackets for scoliosis had been in use intermittently for over a gen-

eration; but that they had failed of their object, chiefly because the muscle factor had been ignored, and because the proper mechanical principles had not been observed in making the correction. These principles, he said, were still ignored in many of the procedures that had lately been brought forward. The mechanics of correcting the torsion and the consequent chest deformity constituted a most important feature. The apparatus exhibited by Dr. Freiberg showed the application of these principles; but the possibility of maintaining the corrective effect, he admitted, had not yet been demonstrated.

Treatment of Scoliosis (Fixed Type) by Plates, Supplemented with Pneumatic Pressure.—Dr. JOHN PRENTISS LORD of Omaha stated that he had found frequent forced corrections under plaster to have rendered the best net results in such cases. The pressure surfaces were greater in casts than in braces, and might, therefore, be made to exert a greater corrective force, and thus maintain a maximum of efficiency. These casts had been fenestrated to the greatest possible extent, especially over concavities of the chest, to avoid chest constriction. The breasts of females were made free by ample fenestra. To gain still more efficiency and to add more pressure over the protruding ribs, he had used air-bags made from sections of the inner tubes of automobile tires, discarded tubes of good quality being used, and being inflated by means of the valve stems of bicycle tires.

A Jacket for the Treatment of Scoliosis.—Dr. MICHAEL HOKE of Atlanta had devised a joint that permitted universal motion and that, at the same time, was of such construction that it could be locked securely in any position in which it was placed. It was merely a matter of ingenuity to apply a series of these joints to the particular individual and the particular jacket in which it was desired to use them. He did not claim that this was as effective as plaster; but stated that sometimes circumstances arise preventing the use of plaster during certain periods, when this jacket might be substituted.

The Treatment of Rotary Lateral Curvature of the Spine.—Dr. B. E. MCKENZIE of Toronto stated that there were two essentially different and opposed methods of treatment: one, forcibly corrective and restrictive; and the other, forcibly corrective, developmental, and educative. The former, while correcting the deformity, failed to improve function; while the latter was effective in bettering both form and function.

A New Scoliosometer.—Dr. JAMES K. YOUNG of Philadelphia presented a new method of transferring the outline and tracing of scoliosis directly to tracing paper. The method, he stated, was simple, inexpensive, and scientifically accurate.

Some Material to Be Used in Padding Plaster Jackets.—Dr. C. F. PAINTER of Boston said that this material was used for the protection of the body from the pressure of the plaster. Ordinary sheet-wadding was packed up with a gauze bandage, in order to lessen the difficulties occasionally met with in the application of the sheet-wadding, which tended to slip.

Dr. JOEL E. GOLDTHWAIT of Boston, opening the discussion on this symposium, said that the most embarrassing question that one could ask the chiefs of the different clinics was regarding what they had accomplished with reference to the rotation in this condition. He himself had been able to do very little with it.

Dr. ABBOTT of Portland, Me., had shown that by putting the patient in the position of flexion, one relieved the locking of the articular processes and put the spine in the position of greatest flexibility. It then became possible to unrotate the spine, so that correction could be made. If the shoulders were dropped and the body bent to the side, one did not have a true rotation. If the shoulder was raised and the same position maintained, the body of the vertebra was rotated.

Dr. L. J. PORTER of Chicago had visited Abbott, and had obtained the impression that failure in trying to correct this deformity had been due to the fact that when the spine was locked, there was no possibility of rotating the vertebræ. The only possibility of correction in this position was in little children, whose ribs were so soft that they could be twisted back into place. Dr. Abbott had succeeded in doing in three or four months what Dr. Porter had not been able to do in years.

Dr. CLARENCE L. STARR of Toronto said that he had obtained a paralysis of the arm from the pressure of a jacket carried over the shoulder. The paralysis had come on three weeks after the application of the jacket, which was not tight. The paralysis had an onset similar to that of the ordinary crutch palsy, and had cleared up in five or six months.

Dr. PRESCOTT LEBRETON of Buffalo remarked that there might be cases of lung trouble, or of flexed uterus, which might be harmed by this sort of treatment.

Dr. F. E. PECKHAM of Providence observed that if such work had been led up to by previous work in that direction, the medical mind having been prepared by a logical sequence of events for this ultimate result, it would have all seemed easy and natural; but the idea had apparently just flashed across Dr. Abbott's mind, and the trick was done. The result had come first, and the explanation afterward.

Dr. C. D. NAPIER of Brooklyn in following out the padding posteriorly over the kyphosis, and in trying to correct the rotation from posteriorly, had been disappointed in the result. Recently he had tried to follow out the idea of padding anteriorly on the ribs, and had found that it made a wonderful difference in the amount of correction obtained.

Dr. H. AUGUSTUS WILSON of Philadelphia asked what was done by Abbott as to changing the shape of the bones, as he felt that the results stated had been such as to make one ask what would prevent the recurrence of the deformity.

Dr. L. J. PORTER of Chicago said that when the first jacket was removed, the patient should be put into another, so as to prevent recurrence.

Dr. S. A. TWINCH of Newark said that his understanding was that Dr. Abbott applied over-correction, which was what was relied upon in the treatment of every deformity except curvature. No one thought of merely correcting bow-legs, but over-corrected them.

Dr. Z. B. ADAMS of Boston said that when the vertebræ had swung around to the side of the convexity in the back, in the dorsal region, and had become wedge-shaped, and when the ligaments on the side of the vertebræ had contracted,—he did not see how Dr. Abbott could untwist these vertebræ and bring them around into position or over-position.

Dr. C. H. BUCHOLZ of Boston reported a new scheme for recording scoliosis. In order to make the records uniform and to get the patient in the same position, Dr. R. B. Osgood of Boston had constructed a frame, with cross-pieces and padding, to hold the patient in the same position each time. Although this position was unnatural, it could be assumed every time. A stereoscopic photograph was used, which gave a beautiful view.

Dr. W. E. BLODGETT of Detroit said that he had never before understood why the vertebræ rotated so in lateral curvature. The explanation was that the raising of the ribs on the convex side produced an increased distance between the costal attachments at the sternum and those at the vertebræ. As the power of the sternum to give was limited, there was a tendency to rotate the vertebræ in the way in which they rotated, producing this rotary deformity.

Dr. N. M. SHAFFER of New York City had claimed, some years before, that deformities should be measured, just as the ophthalmologist measures the functions of the eye. He had compared lateral curvature to torticollis, which was the same sort of deformity in the cervical vertebræ as lateral curvature was in the dorsal. In a case of his own, lateral curvature had been caused by fusion of the ninth and tenth and the tenth and eleventh ribs, two inches from the vertebral column. Removing the fusion cured the curvature.

Dr. WALTER TRUSLOW of Brooklyn considered the *x*-ray as the final court of appeal, but said that it was sometimes difficult to get an *x*-ray taken.

Dr. Z. B. ADAMS of Boston said that fusion of the ribs *per se* did not cause scoliosis. In an examination of specimens in the museum at Boston he had found some that showed two ribs fused together, with no scoliosis whatever.

Dr. R. T. TAYLOR of Baltimore stated that after the appearance of Abbott's article, he had treid, without having suitable apparatus, to correct the deformity by means of posture and strength. The progress of the improvement was much more rapid than any he had before secured.

Dr. C. L. STARR of Toronto said that his colleague and he had found, in connection with the bending position and elevation of the arm, that they had made a marked change in the contour by putting a lift under the foot of the side that was convex, thus tilting the pelvis.

Dr. J. L. PORTER of Chicago stated that Abbott did not profess to correct the curvature at one sitting. The object of the treatment was to compel the rib and the vertebræ to rotate gradually and slowly. The apparatus was not well made, but its principle was correct.

Dr. J. E. Goldthwait of Boston remarked that if prolonged maintenance of the position insisted upon by Abbott were kept up, it might be harmful to the viscera; but it was necessary to maintain it for only an exceedingly short time. He thought it fair to recognize that it was not possible, probably, to maintain permanently the complete correction of all these cases. On the other hand, of the fact that improvement was possible, he thought that there could be no doubt,—and much more rapid improvement than with any other method that he knew of.

Dr. Compton Reilly of Baltimore asked whether the twist in the pelvis had been corrected in Dr. Abbott's cases.

Dr. A. H. Freiberg of Cincinnati felt that there was no reason why, if the spine could be maintained in this position of over-correction, that deformity could not be retained as well as could a club foot.

Dr. J. P. Lord of Omaha said that he had been carrying out the method of relief of chest constriction to a greater extent than he had seen done by many others. The Abbott jackets that he had seen had not been adequately fenestrated. He believed that the deficient aeration, due to the limited fenestration, would have a deteriorating effect. He had found the pneumatic pressure to be superior to the additional pads of felt.

A Consideration of the Carpal Arch, with Its Relation to the Function of the Hand.—Dr. Joel E. Goldthwait of Boston said that the bones of the carpus and metacarpus were arranged in the position of an arch, both transversely and antero-posteriorly, the convexity of the antero-posterior arch being toward the arm. The formation of the first carpo-metacarpal articulation was, he said, very peculiar. It was most important to the function of the hand to maintain these two arches.

A Simple Operation for the Relief of Contraction in Certain Cases of Volkmann's Paralysis.—Dr. Leonard W. Ely of Denver stated that this operation had been first worked out on a specimen in the laboratory. It was found that a simple division of the tissues between the tendons of the flexor sublimis digitorum and the flexor profundus digitorum and the bones in the distal phalanges would release the contraction. In regard to the causation of this condition, he thought that the experimental work of Lorenze and others had failed to prove their contention that it was the cutting off of the blood-supply that produced Volkmann's paralysis. He thought that the paralysis was caused by the injury of the nerve that might have been inflicted at the same time that the bone was injured, and not by the pressure of the splints upon the blood-vessels.

Dr. Sayre thought it possible that there was more than one cause making the contractions in these cases, and considered Dr. Ely incorrect in assuming that the experimental work had failed to show that cutting off the blood-supply would produce this effect.

Dr. G. E. Packard of Denver stated that it had been demonstrated that an elastic bandage would not cause this type of paralysis, but would produce a flaccid paralysis; so that the paralysis in Dr. Ely's case must have been due to the splints.

Dr. H. P. Galloway of Winnipeg had operated on several cases of ischemic paralysis by lengthening all the flexor tendons in the upper forearm above the wrist. As soon as they were all divided, the different fasciculi being kept together with forceps, it was easy to straighten the fingers. He could not reconcile this fact with Dr. Ely's hypothesis.

Dr. Ely said that he could not find that paralysis had ever been experimentally produced in an animal, unless the nerve had been included in the ligature. Although it was usually assumed to be caused by tight splints, it had never been proved that a temporary stopping of the blood could cause these particular anatomical lesions.

Dr. Charleton Wallace of New York City asked whether this severing of tissue was within or without the tendon sheath.

Dr. Ely replied that it was without the tendon sheath immediately attached to the proximal phalanx.

Plates for Static Foot Troubles.—Dr. William E. Blodgett of Detroit said that one was justified in making any kind of plate that would stop pain and still allow of function. A plate made to conform to the shape of the sole was often not so successful as one of an arbitrary shape. In making the cases no effort had been made by him to get the foot into the shape that it would take if it were not flat. The pain, in the majority of cases, he stated, could be stopped by a very simple plate. He had found that the ordinary foot would tolerate 11 per cent. of rise.

The Mechanical Treatment of Hip Disease.—Dr. George E. Packard of Denver believed that if sufficient mechanical treatment, in addition to proper hygienic measures, were instituted early in hip disease, a cure would often be secured with motion. Every means should be used in the early stages to effect such a result. Traction, fixation, and protection from weight-bearing should be persisted in as long as there seemed any possibility of obtaining such results. Early weight-bearing should not be allowed, as it favored ankylosis, absorption, and enlargement of the acetabulum. Dr. Packard thought if stiffness persisted after two years of treatment by traction, fixation, and protection, and there seemed to be little probability of recovery with motion; and if there was absolute freedom from sensitiveness, then weight-bearing, with fixation to prevent flexion and adduction, was the treatment of choice. Ankylosis was to be desired in many cases as the best possible result for the future comfort and permanent cure of the patient. The treatment should not be one of routine, but should be selected according to the indications in each individual case.

Results in Hip Tuberculosis After Mechanical Treatment (Without Traction) and Hygiene.—Dr. Henry Ling Taylor of New York City reported the cases of seven patients treated by means of the Phelps brace. Five children had their splints removed in the summer of 1910. All but one child had abscesses. They were all early cases, and of at least average severity. The average duration of the treatment to the time that the splints were removed was three years. In one case, which was a double one, a moderate flexion was corrected since the removal of the brace, and two patients had subsequent treatment for a weak knee. These two patients still used crutches, the others walking well without support. The abscesses healed and the patients regained good health. In all but one case, in which there was thirty degrees of motion at the hip joint, there was only slight motion, and the position of the leg became excellent. In none did the shortening exceed one inch except in the two girls with weak knee. *X*-ray plates showed more or less enlargement of the acetabulum, moderate erosion of the head (except in two), and the head in the acetabulum.

Dr. Robert W. Lovett of Boston, opening the discussion on the papers of Drs. Packard and Taylor, stated that orthopedists were not sufficiently careful about looking after the muscular atrophy following joint injury. He thought that more persons had stiff, irritable knees due to that than to any other cause. There was also a large element of disuse in this condition. He remarked that athletes would not allow their joints to be fixed, but used them with light bandages. Accompanying the muscular atrophy in some cases there was a distinct atrophy of the bone, he said, which diminished to one-third its normal width. A good many of the effects seen in chronic joint disease were possibly due to bone atrophy.

Dr. L. W. Ely of Denver asked how weight-bearing could cause a less amount of atrophy of the limb than a treatment that caused function of that limb. He said that muscular spasm was nature's method of putting the joint at rest, and could not cause trauma to the joint. It was motion that produced the pain. Trauma might have a slight causative effect in joint tuberculosis, but scarcely in the bone. When the tuberculous focus occurred in the bone the bone was subject to trauma. The only way to find the solution of these questions, he thought, was to ask "Why?" when any opinion was advanced regarding fixation and traction.

Dr. H. A. Wilson of Philadelphia said that weight-bearing was not the only method applicable to bony ankylosis, but that it got rid of some of the results of uncarefully applied fixation and confinement in bed. The physical improvement of twenty patients with tuberculosis of the hip who had been at Atlantic City all winter had been phenomenal, he stated. They never slept with warmth in their room, and had very little fixation. This showed that the emaciation seen when there had been fixation in bed and disuse was not present with this treatment.

Dr. F. H. Albee of New York City said that he could exhibit *x*-rays in which there was shown such tremendous rarefaction of the head of the femur that it gave no more density than the softer tissues in which it was embedded. He thought that this type of cases should have weight-bearing removed, and be either placed in bed with traction or put into a brace that would prevent weight-bearing, if not produce traction.

Dr. Virgil P. Gibney of New York City did not consider the *x*-rays to be always as reliable as some people thought. He stated that some radiologists thought that rarefaction meant tuberculosis, and others did not agree

with this view. Dr. Gibney was a believer in the value of a full history of the patient. In his later work he had used the plaster spica in all early cases. The results had been so uniformly good that he had wondered whether the condition might not be an infection of some kind. He was trying to get some ambitious member of the staff of the Hospital for Crippled and Ruptured to collect two or three hundred of these cases and get their end results. He had found that good radiologists could not tell whether it was a degenerative or a regenerative process that was going on in the head and neck of the femur. He himself thought that many of these cases were regenerative, and threw out bone to protect the parts about the joint.

Dr. Joseph Root of Hartford said that in every case there was a sensitive stage which could be distinguished without the aid of *x*-rays. It seemed to him that the child should be kept quiet at that time. He did not believe that any perambulatory extension could be of as much protection to the joint as the ordinary fixation.

Dr. Charleton Wallace of New York City three years before had examined a collection of pictures of coxa varas and tuberculous lesions. He had found that the plates that showed the least amount of bone destruction were the ones that had had only plaster-of-Paris treatment and rest in bed. The cases that had had brace treatment had more destruction of the head. Some had pathological displacements. The solution of the problem, he believed, would be in raising the resistance of the patients. They should be kept out of doors all the time, should get nourishing food, and should be kept from brain fatigue.

Dr. G. G. Davis of Philadelphia stated that there were two kinds of spicas, the short and the long. He was opposed to the former, and believed that a long spica, from the waist to the toes, gave fixation and rest, while the short spica did not. He considered absolute rest in bed necessary during the active stage of the disease, with as much fixation as could be obtained. After the patient was able to get out of bed the spica should be removed. Crutches should then be used, with a high shoe on the opposite side. Instruments should be resorted to only when all active symptoms had subsided. He thought that children did better at hospitals than at convalescent homes, where, although the general condition improved, the local condition deteriorated.

Dr. B. E. McKenzie of Toronto said that he had thought that traction was meant to serve a double purpose: that of keeping the head of the femur in such a position that it would not be brought violently into contact with the acetabulum; and that of preventing deformity. Cure of the disease was obtained, in his opinion, by enabling the resistance from within to throw off the affection. The part in which the tuberculous lesion existed should be exposed for hours each day to the sunlight, and this treatment should be continued for months. He believed that no long brace had ever supplied complete fixation of the joint.

Dr. C. J. Jager of New York City said that there should be a distinction drawn between the short spica and the Lorenz spica. The short spica would not fix the hip, but the Lorenz spica would fix it absolutely.

Dr. T. H. Myers of New York City stated that the focus was sometimes in the epiphyseal line, and sometimes in the acetabulum. In the former case the amount of immobilization needed was very different from that required when the findings showed that the focus was in the joint itself. He referred to a case in which the *x*-ray had shown a destruction of fully one-half the head, and said that he had seen the case two years after this and had found a regeneration of the head.

Dr. V. P. Gibney of New York City remarked that spindle-shaped femurstibias were no longer found, all being of good size at the present time.

Dr. J. E. Goldthwait of Boston stated that all were agreed that hip disease was a general disease, and that local treatment for it amounted to no more than protection. He thought that bone atrophy did not come from disease, but from disuse. In looking up the end results in some hospital cases that had disappeared from observation he had found that some of these patients had taken care of themselves better than those being treated. He mentioned the fact that the results obtained at a hospital in Switzerland by direct exposure to the sun at a mountain resort were superior to those obtained at the seashore or by any other treatment.

Dr. J. P. Lord of Omaha remarked that when the condition indicated that the head of the bone was liable to break down, traction was the indication. He did not consider the amount used now adequate to prevent the destructive process and mechanical displacement.

Dr. Wallace Blanchard of Chicago stated that it was friction that did the destructive work in the hip joint in the majority of cases. Lateral, as well as longitudinal, movement was necessary to this; and he had advised using both kinds of extension in order to produce traction in the direction of the neck of the femur.

Dr. Packard, closing the discussion, said that the object of his paper had been to emphasize the necessity of treating these cases according to their type and the stage of the disease.

Dr. Taylor said that there were two factors to consider, general and local hygiene. Both should be appreciated in their details and their divergent requirements in different classes of cases.

Further Observations on the Use of Intraarticular Silk Ligaments in the Paralytic Joints of Poliomyelitis Anterior.—Dr. W. W. Plummer of Buffalo presented this paper, which he had written in collaboration with Dr. Bernard Bartow of Buffalo. He said that during the past year they had employed this procedure exclusively in fifty joints. Many of the cases had been too recently operated on to be more than suggestive of the improvement anticipated, but it might be confidently stated that the procedure had been developed to a point that took it out of the experimental stage. While it was not advocated as an exclusive mode of treatment, it might become so in some cases. The joint should be carefully protected for a long period after the operation.

The Results Obtained by the Implantation of Silk Ligaments and Tendons for Poliomyelitis Paralysis.—Dr. Nathaniel Allison of St. Louis considered artificial tendons more valuable than the older operation for stability, arthrodesis. His method was to imitate the pull of normal tendons by means of silk cords, inserting these in the bone above and below and running the silk tendon in the sheath of the paralyzed tendon. In no case had there been infection, nor had the inserted silk caused trouble. The use of one or another kind of silk artificial ligaments or tendons he thought preferable to arthrodesis in children.

The Industrial Education of the Crippled and Deformed.—Dr. H. Winnett Orr of Lincoln stated that the care of cripples was a part of the modern tendency toward the prevention of dependency. Even after adequate hospital care many orthopedic patients lapsed into dependency for want of an occupation. It was necessary, therefore, that some kind of employment should be selected for these persons by a competent orthopedic surgeon, who should have subsequent supervision over them. The ideal arrangement, he considered, was for the hospital and training school to be combined in one institution. There was a great need for such institutions, only a small number of which were in existence. Cities and States should make such training in connection with orthopedic hospitals a part of their educational system .

Dr. H. Tunstall Taylor of Baltimore said that in Baltimore they had had the cooperation of both the city and the State in the educational training of such children. As soon as they were able to go they were sent to the schoolroom, where the regular school system of Baltimore was followed. After the child had been there for several months it was able to take its place in the proper grade in the public school. There was a definite selection of occupations suitable for the individual cases.

Dr. W. G. Stern of Cleveland stated that he had visited the New Jersey Training School for Feeble-Minded and Defective Children at Vineland, and that it was wonderful what educational training had done there to improve the arm muscles of children with spastic paraplegia, enabling them to learn trades. With a slight change the plan of this institution might be adapted for use in the conduct of schools for crippled children in other States.

Dr. C. H. Jaeger of New York City considered it remarkable what could be done with these cases. He thought that these poor defectives should not be consigned to the scrap heap before an attempt had been made to do something of this kind for them.

Dr. Orr did not think that such children should be put into competition with normal children, and said that they needed special educational methods.

An X-Ray Study of Gastrointestinal Findings in Multiple Arthritis.—Dr. George R. Elliott of New York City gave a lantern slide demonstration of these plates, nine being taken from ten selected cases of walking patients afflicted with classical types of chronic polyarticular arthritis. Nine showed ptosis of some portion of the viscera or stasis in the stomach or colon. One showed a markedly dilated stomach; and three, enlarged spleen. His conclusions were that, while the primary etiology of the disease did not lie here, it was an important factor,

which tended to keep up a vicious circle. The original infective toxins in many cases soon ceased to act; but the abdominal conditions, acquired and otherwise, fed the already diseased joints. He felt that the physician who neglected to have a proper examination, *x*-ray and otherwise, of the gastrointestinal tract, neglected his patient. Most of the abnormal intestinal conditions were remedial.

Some Conditions of the Pathogenesis and Treatment of Toxic Polyarthritis.—Dr. F. W. Nathan of New York City said that there existed very little definite knowledge of toxic polyarthritis. The general opinion seemed to be that there was a definite joint disease as the result of autointoxication from the intestinal tract; but in the reports of the cases of undoubted autointoxication from this source no mention of joint symptoms was ever made. The conception that a toxic joint condition was the result of intestinal putrefaction seemed to rest on the basis that in a certain percentage of the cases there was indican in the urine. It had, however, been disproved that indican in the urine was of any diagnostic importance; and it had not been definitely shown that the cases reported as toxic arthritis of intestinal origin had any connection with the intestines. The treatment, he said, must be based upon general principles and directed toward the general condition. Care in the examination, attention to detail, and careful study of the individual cases were necessary if treatment was to be successful.

The Etiology of Chronic Arthritis.—Dr. Leonard W. Ely of Denver stated that the cause of this group was still a matter of debate, but the infectious theory had been gradually growing in strength. He believed that all these diseases were infections, every bone and joint disease whose exact cause was known being infectious. He thought it better for the present to believe that a number of different organisms might be responsible for these diseases, especially as this view agreed with clinical evidence. In many of these cases of chronic joint disease a distinct source of infection had been found; and in some, the removal of the source of the infection had been followed by an improvement or a cure in the joint disease.

Cases of Acute and Chronic Arthritis (Acute Toxic Arthritis, Arthritis Deformans, Rheumatoid Arthritis, etc.).—Dr. Michael Hoke of Atlanta had studied a series of forty-seven cases, extending over fourteen months, without regard to classification; and had found running through the whole series, while they were acute, a profound disturbance of metabolism. As the patients got better their metabolism became nearer to the normal. When their protein was cut down the excretion of uric acid rose coincidently with improvement in the patients. An ordinary healthy human being, he thought, was able to take care of intestinal putrefaction. The arthritic patient, however, could not take care of it. It harmed him, and should always be avoided.

Dr. J. E. Goldthwait of Boston, opening the discussion on the last four papers, said he was glad that the group of so-called mechanicians had gone so far as to recognize the fact that joint symptom was not a disease. It seemed to him that in the abdominal organs was to be found an explanation of one of the difficulties under which the human family labored, one of the penalties that they paid for being bipeds being a maladjustment of their viscera. This was of no consequence unless it led to some disturbance. A series of cases had been measured in the dissecting room by himself and Dr. Brown, and they had found that the anatomic types usually considered normal were rather uncommon. Many people, for instance, had only half of the small intestine. Of course they were not well nourished. The possibility that infective organisms might travel up the small intestine from the colon and get to a point at which absorption could take place was increased in such persons.

Dr. J. L. Porter of Chicago referred to an interesting occurrence in animal experimentation. A nurse, who had formerly had severe tonsillitis, suffered with a chronic arthritis of the ankle joint. The tonsils were removed and the ear of a rabbit was injected intravenously with an emulsion made from the contents of an infectious focus in the larger tonsil. The ear of another rabbit was injected at about the same time with infective material secured at autopsy from the body of a professor in the Chicago University who had died with an acute pyogenic infection involving all his joints. Both rabbits developed the same type of infection, the changes in the joints being in the same location in the rabbits as in the patients from which the material injected had respectively come.

Dr. S. M. Cone of Baltimore wished to know whether the internal secretion itself, as a poison, produced the joint trouble, or whether it did so by its action on whatever organism might be present.

Dr. C. F. Painter of Boston said that a great many infections did not produce any symptoms, a great many anatomic disarrangements did not give rise to disturbances, and probably a great many internal secretions might be disturbed without causing anything that could be recognized as a clinical disturbance.

Dr. A. H. Freiberg of Cincinnati thought that the orthopedic profession was in danger of falling into a kind of scientific empiricism. Unless they confined their studies more closely to the joint phenomena they were likely to be carried into the realm of internal medicine without getting much nearer to the solution of the question.

Dr. J. J. Nutt of New York City had noticed that in the treatment of tuberculous joints those children who were allowed free action of every joint possible and lived as normal a life as was consistent with care of the joints affected did remarkably well in comparison with those treated with more or less confinement. He had also followed out this treatment in some chronic rheumatoid arthritis cases, and thought that a great deal might be said in favor of permitting and encouraging all functions of the body that did not interfere with the correct treatment of the joint.

Dr. G. R. Elliott of New York City referred to Still's disease and said that studies made by him had shown that it could not be longer regarded as a distinct disease entity. Still had claimed that it differed from arthritis in adults, in which the enlarged spleen was not found. In four of the ten cases that Dr. Elliott had just reported the spleen had been much enlarged.

Dr. F. W. Nathan of New York City said that he had merely wished to call attention to the only possible method of solving the problems or progressing in the study of these conditions. Unless all the cases were taken, and definite clinical entities formulated as nearly as possible, separating the cases and bringing them into connection with definite pathological and clinical conditions, nothing could be learned about these cases. The joints, he said, were a mechanical apparatus. It made very little difference what the process in the joint was, the mechanical conditions were impaired; and the impairment was apparently the same in all, so that there was difficulty in differentiating the joint conditions.

Dr. F. E. Peckham of Providence felt that a very large number of cases were due to faulty physiology in the abdominal region somewhere. He thought that the time might at last come when most of these joint diseases, with their different pathological conditions, would be found to be due to one main thing. The treatment, of course, must then be applied to that thing, instead of to the end results in the joint.

Dr. L. W. Ely of Denver thought that, instead of building up clinical entities and studying their pathology, they should build up pathological entities and mould the clinical manifestations upon them. The changes in the bone and cartilage represented merely the disease of the essential elements of the joint, which are the synovia and the bone-marrow.

Stereoarthrolysis, Restoring Mobility in Bony Ankylosis of the Joints.—Dr. R. Tunstall Taylor of Baltimore said that ten months before he had begun laboratory and animal experimentation to determine a liquid, absorbable, animal substance that could be sterilized and injected by syringe between the denuded ends of the bones entering into the proposed new-made articulation, and that would immediately solidify in such a manner as to prevent contact for some six or eight weeks before being absorbed. Yellow wax, 0.1, and lanolin, 2.5, were the chief substances and proportions determined upon after careful study, melting at about 130° to 135° F. The advantages of this method were, primarily, the prevention of the reformation of bony adhesions in properly done cases; the absence of pain, none of the cases requiring any anodyne; the speedy voluntary ability to move the joint, as compared with other methods; the absence of fever and suppuration; the hemostatic effect of the wax on the bone ends; the absence of hematuria and ecchymosis, and the rapidity with which the operation could be done compared with other methods.

Absence of the Bony Femoral Heads and Necks.—Drs. John Ridlon and H. B. Thomas of Chicago were the authors of this paper, which was read by the latter, who said that absence of the bony femoral heads and necks, supposedly occurring in rachitic children, was a rare condition, as proved by the bone pictures taken later in the life of the individual cases, in which bone salts had been deposited. *X*-ray pictures taken at different angles would sometimes give evidence of a head and neck in a supposedly congenital absence.

Bone Transplantation in the Treatment of Club-Foot, Pseudarthrosis and Pott's Disease.—Dr. Fred H. Albee of New York City stated that in case of club-foot in older children, in whom adduction of the front part of the foot predominated, a wedge of bone had been ingrafted into the scaphoid; in several instances, with most gratifying results. In several cases of pseudarthrosis of long standing a strip of bone about five inches long by one-half by one-third from the crest of the healthy tibia had been inlaid into the cortex of the end of each bone fragment and fixed with heavy kangaroo tendon through drill-holes in the recipient bone-fragments. A firm union had been secured in each case, and in one in which a Lane plate had previously failed. In thirty-two cases of Pott's disease a prismatic shaped piece of the tibia had been implanted into the spinous processes of the diseased vertebræ, with most striking results.

Dr. S. M. Cone of Baltimore, opening the discussion on the last two papers, asked whether it was easy to get a protected wound, to protect the transplant where Dr. Albee had to cut into the contracted tissue on the inside and put in the transplanted scaphoid.

Dr. G. G. Davis of Philadelphia believed that the present means of treating Pott's disease were so unsatisfactory as to justify resorting to radical measures. Even after a quiescent stage had been reached the deformity increased. The disease extended over many years, and frequently broke out afresh and killed the patient. He was a firm believer in the regeneration following the transplantation of bone in these various processes. He thought that the procedure was not so serious as to preclude its being used.

Dr. John B. Murphy of Chicago said that Dr. Albee's treatment was the first ray of light on the management of spondylitis. It was a prophylaxis against deformity. Putting in a bone was easy to do. One could apply the treatment of the transplanting of bone from the same individual, having contact of bony surfaces with the periosteum, as soon as the child began to show stiffness and fixation; and there would be a uniform regeneration of the bone in the transplant. A graft of bone, once transplanted, would not grow in length, but only in circumference. If the periosteum was left on, the bone would not spread. The entire rôle played by the graft, he thought, was that of supporting the Haversian vessels. The graft must be human bone. He believed that this treatment would be ideal treatment for ununited fractures; and that when there was a defect in development these grafts might be used with effect.

Dr. J. T. Rugh of Philadelphia asked whether it made any difference which side of the graft was placed to the firm half of the process. He also asked whether in certain fractures of the neck of the femur that refused to unite, the insertion of a piece of this bone would tend to bring about bony union.

Dr. B. R. McKenzie of Toronto had not noticed that anything had been said about transplanting bone when there was deficient bone congenitally. Nothing had been said by Dr. Thomas about complete absence of the femur. Dr. McKenzie had seen four cases in which there had been nothing except an indefinite nodule at the upper end to indicate where there was a remnant of the femur left.

Dr. Rugh said that in a case of congenital absence of the lower two-thirds of the tibia he had substituted the fibula, and that it had become practically of the same size as the tibia, and was keeping pace with the growth of the latter.

Dr. T. H. Myers of New York City said that two of Dr. Albee's *x*-ray illustrations showed the diseased bodies separated by considerably more interval than they would have been before he had straightened them. The old idea had been that these would not heal unless the surfaces came together.

Dr. Goldthwait of Boston stated that he had seen a case in which both fibulæ had been transplanted to take the place of an absent tibia. There was still deformity of the foot, but both legs had developed so that the child could run about and play without difficulty.

Dr. H. P. Galloway of Winnipeg was a firm believer in the principle that if ankylosis could be brought about in tuberculous joints the disease would be cured. This was not easy to do in the sacroiliac joint. He asked whether the transplantation of a bone graft into the scroiliac joint would bring about ankylosis in that joint.

Dr. Abraham Jacobi of New York City had found that his fractures would heal readily when he fed his patients on phosphorus. His cases of Pott's disease and tuberculous ankles got decidedly better in a shorter time with phosphorus than without it. Tuberculous disease, not only in the lungs, but in the soft parts and in the bones, would do well when systematically treated on arsenic. One should not forget that there were other things besides operations, and that a great deal could be done to strengthen and purify the system for the purpose of making an operation more successful. Arsenic, he had found a semi-specific in tuberculous disease. He thought that better results would be obtained if the patients were in good condition, and that this could be brought about by the use of phosphorus and arsenic.

Dr. J. B. Murphy of Chicago said that the tendency had been to go entirely away from medication, but that surgeons were coming back to the things that combated tuberculosis in bone, lung, and every other organ.

Dr. Albee, in closing the discussion, stated that the disadvantages in the use of metal and other foreign bodies were obvious. One could not trust metal to hold tension in bone. If motion persisted in tuberculous disease it constituted a danger and favored a relapse of the condition. The autogenous transplantation of bone was very important, as Dr. Murphy had said. The graft should be placed against the unbroken side. When he had first begun, Dr. Albee had placed the cut side next to it; but he had since turned the graft around, split the periosteum, and put the periosteal side against the unbroken spinous process. He thought that the plug of bone would be worth trying in the case of fractures of the neck of the femur. He saw no reason why the transplant should not be put directly across from the sacrum to the ilium, as this would fix it more simply and with less operative procedure.

Congenital Absence of the Fibula.—Dr. Prescott Le Breton of Buffalo reported ten cases of this rare condition, one of which was operated upon with satisfactory results; he also showed some photographs and *x*-rays of these cases.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. A. R. Shands of Washington, D. C.; *Vice-Presidents*, Dr. J. D. Griffith of Kansas City and Dr. David Silver of Pittsburgh; *Treasurer*, Dr. G. G. Davis of Philadelphia; *Secretary*, Dr. Ralph R. Fitch of Rochester, N. Y.

The next meeting will take place at Washington, D. C., in May, 1913.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Twenty-second Annual Meeting, Held at Richmond, Va., September 3, 4 and 5, 1912.

The President, Dr. William D. McFee of Haverhill, Mass., in the Chair.

Report of the Committee on Direct Continuous Current, Including Electrolysis, Electrochemical Surgery, Ionization, and all Apparatus Connected Therewith.—Dr. G. Betton Massey of Philadelphia reported that there was nothing new in the way of apparatus under this head. The committee felt that it was still necessary to reiterate the necessity for accurate meters and controllers that have sufficient resistance and smoothness of current increase to permit the application of the current strengths that would be employed without sudden increase or decrease. A great impetus had been given in England and Continental Europe to the newer developments in medicinal ionization

Report of the Committee on High Frequency Currents.—Dr. Frederic de Kraft of New York reported that during the past year many different types of multiple spark gap had been constructed and tried. He had succeeded, with the help of Wappler Brothers, in constructing a multiple spark gap of the simplest possible type, with nine very small gaps. The result in increasing the rate of oscillation to be obtained from the D'Arsonval spiral was truly amazing. When the bipolar method was used there was entire absence of Faradic effect. The brush effect—the Oudin effleuve—was more marked, many times longer, and of greater density.

Report of the Committee on Phototherapy.—Dr. Edward C. Titus of New York read this report. It contained a continuation of the observations offered last year upon the physiochemical effects of the ultra-violet and blue-violet rays upon both normal and abnormal conditions of the skin; an abstract of an article upon the beneficial effects of strong, clear sunlight in the treatment of bone tuberculosis; and an account of investigations made during the past year by Dr. T. T. Gaunt of New York and the writer upon the anesthetic action of true blue light, the method of employment, apparatus, and therapeutic applications.

Report of the Committee on Radiography, Radiotherapy, and Apparatus.—Dr. G. E. Pfahler of Philadelphia reviewed in detail the advances made along this line during the past year.

Report of the Committee on X-Ray and High Frequency Tubes and Apparatus.—Dr. Frederick M. Law of New York in this report called attention to the points of interest in connection with *x*-ray tubes constructed and used in a practical manner during the past two years.

Epidemic Poliomyelitis.—Dr. William Benham Snow of New York drew the following conclusions: Acute poliomyelitis, an infectious disease, possibly contagious, is characterized by congestive infiltrations, particularly marked in the meninges of the spinal cord, sometimes involving the meninges of the brain and the substance of the cord. The indications after the onset are to increase local resistance and promote the elimination of the infiltration, particularly from the cord and meninges, as soon as possible, in order to relieve the pressure upon the ganglion cells, and thereby restore their function, relieving the resulting paralysis. For removing infiltration the static wave current applied with marked energy has been demonstrated to be remarkably effective, which is undoubtedly due to its mechanical effects upon the tissues. For increasing the local resistance and possibly removing the virus, radiant light and heat, the direct D'Arsonval current and static wave current are remarkably effective, as evidenced clinically, and should be employed in the earliest stages and until recovery is complete. In the subsequent stages the static wave current to the spine, radiant light and heat and mechanical vibration to increase the metabolism in the paralyzed parts, together with voluntary exercise and exercise induced by electrical stimulation, as with the static induced current, are indicated. Under such technique, except in the violent early cases which promptly succumb, the prognosis is good when cases come early under observation, fairly good in later cases, and beneficial in most neglected cases.

Exploitation of Apparatus; Suggestions for Reform.—Dr. A. B. Hirsh of Philadelphia in this paper made a plea for reform in the marketing of physical treatment apparatus in the United States. The statements made by many manufacturers regarding their apparatus were often indefinite, inaccurate, exaggerated, and misleading. This Association should take a firm stand for the removal of this abuse. The time had come not only for separate annual reports on all electrical apparatus, but for investigation and report on the printed claims for their efficiency. By such official action this organization would place itself in its special field on the same high level attained by the American Medical Association which authoritatively tested and classified all drug remedies.

The Relief of Localized Arterial Spasm by Electricity.—Dr. Frederic de Kraft of New York read this paper. Arterial spasm resulting from autotoxemia, sources of local irritation, excessive use of tea or tobacco, the emotions, and overeating might be successfully treated by the general application of the d'Arsonval current, followed by a thorough application of the resonator effleuve to the cervical and dorsal spine. The wave current applied to the abdomen was valuable in warding off future attacks.

Some New Modalities.—Dr. Arthur W. Yale of Philadelphia described a new mode of administering the static current, to which the term static condensed current had been applied. He also described his method of administering ozone, in which the generator was connected in the usual manner to a source of high potential current, and in place of the bulb a tank of pure oxygen was attached by means of a rubber tube.

Examining and Recording Chronic Cases, with the Treatment of Some by the Continuous Current.—Dr. J. W. Torbett of Marlin, Texas, made a plea for a thorough and systematic examination of every case. Unless this were done, important conditions might be overlooked. In the climate in which he lived it was often impossible to get a current from the static machine. Under such circumstances the galvanic current could often be used with beneficial results.

The Present Status of High Frequency Desiccation.—Dr. William L. Clark of Philadelphia said desiccation should not be confounded with fulguration, or with high frequency cauterization and coagulation. The first devitalized by drying the tissue; the second shocked and produced hyperemia, but did not destroy; and the third was essentially the same as the ordinary cautery, though perhaps deeper in effect. The desiccation spark was not hot enough to carbonize, but of sufficient heat to cause rapid dehydration of the tissue, rupturing the cell capsule and converting the area treated into a dry mass. The initial current was obtained from a static machine of large output and stepped up by an accurately attuned resonator. For superficial desiccation one pole was used; for deeper destruction the bipolar method was employed. While this method of treatment had its limitations, its field of utility was distinct, whether used alone or in conjunction with operative or other measures.

Treatment of Splenic Affections by Diathermy and the X-Ray.—Dr. Frederick H. Morse of Boston reported several cases of autointoxication with enlarged spleen which he had successfully treated by the *x*-ray and the direct d'Arsonval current.

Further Information Concerning the Double Spark Gap Static Current of Electricity.—Dr. Francis B. Bishop of Washington, D. C., gave a technical description of his method of using the double spark gap static current of electricity.

A Résumé of 400 Cases of Tuberculosis in Which the X-Ray Has Played an Important Part.—Dr. J. D. Gibson of Denver, Colorado, said he had used his method of treatment on 400 cases during the past fifteen years. Eighty-five per cent. of the cases were still living. The cases included all stages of the disease. The treatment was particularly applicable to the second and third-stage cases. He did not consider any case beyond hope of improvement. In addition to the ordinary hygienic and dietetic measures, he applied the *x*-ray alternately to the front and back of the chest, the treatments being given every other day. In addition he used the static brush discharge and ozone inhalations, although he did not attach much importance to the latter method of treatment in these cases.

High Frequency Electricity in the Treatment of Exophthalmic Goiter and Perverted Thyroid Secretion.—Dr. William G. Lewi of Albany, N. Y., said the conclusion seemed inevitable that all the symptoms of perverted thyroid secretion were due to the effect of the thyroid toxin on the sympathetic nervous system, and that treatment with high frequency electricity gave better and far more permanent results than any other method of treatment, excepting where a resort to surgery was necessary. In all cases of exophthalmic goiter where an operation was to be performed the patient should have as a preliminary to operation a course of high frequency treatment, to the end that the distressing symptoms might be lessened, if not altogether relieved, and the patient put in the best possible condition for any surgical procedure that might be required.

Rheumatism.—Dr. Rosa D. Wiss of Meridian, Miss., reported a case of long-standing rheumatism which was quickly relieved by the direct current, anodynes locally, and eliminative treatment.

Lessons from Failures.—Dr. F. Howard Humphris of London, England, in this paper gave as the most common causes of failure the armamentarium, inadequate knowledge, unsuitable cases, lack of perseverance, inattention to detail, over-confidence or lack of confidence, fatigue, idiosyncrasy, electrophobia.

Fulguration and Thermoradio-therapy—A Preliminary Report.—Dr. William Seaman Bainbridge of New York gave a preliminary report of the tests now being carried on at the New York Skin and Cancer Hospital by the Research Department, in the treatment of malignant new growths by fulguration and thermoradio-therapy. (See Medical Record, July 6 and 20, 1912.)

Measurement of Röntgen-Ray Power by Tousey Method.—Dr. Sinclair Tousey of New York summarized as follows: A portion of the film is exposed to 1/10 of a candle power of incandescent electric light for 1 second at a distance of 1 meter; or to the equivalent 5 seconds with a 4 candle power lamp at a distance of 14 meters. Other portions of the film are exposed to the *x*-ray at 1 meter for different numbers of seconds. The film is fully developed. If 10 seconds of *x*-ray produces the same density as 1/10 C. P. M. second of incandescent light, the *x*-ray is 1/100 Tousey power.

Treatment of Chronic Deafness by High Potential Electric Currents.—Dr. D. H. Yates of Madison, Fla., reported several cases of chronic deafness, including one case of a young man who had been deaf since birth, successfully treated with the static current.

The Static Charge.—Dr. Charles F. Mills of New York City in this paper gave some facts as to the nature, origin, location, absorption index, direction of transmission and dissipation of the static charge.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. F. Howard Humphris, London, England; *First Vice-President*, Dr. G. E. Pfahler, Philadelphia; *Second Vice-President*, Dr. Edward C. Titus, New York; *Secretary*, Dr. J. Willard Travell, New York; *Treasurer*, Dr. Emil Heuel, New York; *Registrar*, Dr. Frederick M. Law, New York; *Trustees*, Dr. William D. McFee, Haverhill, Mass., and Dr. Frederick H. Morse, Boston.

Place of next meeting, New York City.

Miscellany.

The Doctor His Own Surgeon.—Paul Reclus has commented on the courage and stoicism necessary for the act of what he calls "autotomy," or surgical operation upon one's own body. He has described at some length four examples of this heroic procedure. The first story is that of a French surgeon who, having acquired a small outgrowing tuberculoma of the right index finger following an operation wound, determined to excise it under cocaine anesthesia. This he did, surrounded by his class, in a curiously unsurgical way, by fixing the instrument—first a scalpel, then a sharp spoon—in the left hand and performing all the necessary movements with the diseased *right* hand. In spite of this novel technique the result was quite satisfactory. His only discomfort was a little nausea at the unpleasant sensation of scraping his own periosteum; this was, however, corrected by a sip of hot coffee. In the second case the surgeon operated on himself for bilateral ingrowing toe-nail, apparently without pain and with absolutely satisfactory result. The hero of the third story was a Turkish military surgeon attached to Professor Reclus's own clinic, who was operated on for double inguinal hernia under local anesthesia with such complete success that he determined to remove for himself a troublesome varicocele. The procedure was quite painless and the result perfect. The fourth "autotomy" was performed by M. Regnault, a naval medical officer, who was led to undertake a radical cure of his own hernia. He anesthetized the area of operation by injecting cocaine into the several layers of tissue concerned, after a preliminary injection of morphine into the subcutaneous tissues of the thorax. He guarded himself from disaster by enlisting the help of two colleagues, who stood by prepared for action in case they were needed. However, all went well, and there was neither pain nor mishap.—*The Lancet*, September 21, 1912.

The Question of Fees.—G. W. McGregor states that fees among general practitioners have not advanced commensurately with the cost of living. This rapid age demands quick service, which necessitates the telephone and the automobile, each of which increases the expense of doing business. Formerly a few hundred dollars sufficed to equip the stable, whereas now the first cost is doubled and quadrupled, and the upkeep is beyond computation. It is self-evident that this state of affairs leads to one of two conclusions: larger fees or bankruptcy. Following the line of least resistance leads to the latter. No thinking layman will deny the fact of the large increase in cost of the finished product of the medical college—the doctor—a product that was nurtured through the high school, groomed through the preparatory school, trained in the academic college, moulded in the medical school, finished in the hospital, and polished in the postgraduate school—with spurs to win in the running. The man well dressed has more self-respect than the man shabbily clad. His horizon widens, and his chest and waist measurements expand. To him life seems worth living. But to the average practitioner even the low eminence of a good living in its broad sense is denied him on the basis of fees as they are listed to-day. The fees, in the rural sections at least, are certainly too low, and the fear of protest by the family against a rise is not well founded, judged by actual demonstration in those towns where the rise has been adopted. A little banter about the "doctors' trust" is only a pleasantry, and the higher fee is as cheerfully paid as the lower. The demand of medical schools for a higher preparatory education, and the necessity of maintaining a higher level through the entire course, means a larger outlay of money which must be recouped in practice. No man who rightly and modestly esteems his ability can preserve his self-respect by accepting a pittance for his services. No man who has to worry over his finances can do his best work. It hampers him at every step, cramps his mind, and starves his body. Let the fees be advanced.—*New York Medical Journal*, September 14, 1912.

A Physician to Guide the Destinies of the Chinese Republic.—Dr. George Ernest Morrison, who for fifteen years has been the *London Times'* correspondent at Peking, has been offered and has accepted the position of political adviser to the President of the Chinese Republic. Dr. Morrison was born in Victoria, Australia, in 1862, and studied at Melbourne and Edinburgh Universities. When only twenty years old he undertook a pioneer expedition to New Guinea. The next few years saw him, now roving, now practising medicine, in this country, the West Indies, Spain, Morocco, and ultimately in the Far East. His celebrated walk of more than two thousand miles across Australia was rivaled by a three-thousand-mile walk across China, and then by a walk across Manchuria to Vladivostok on the Pacific. Dr. Morrison traveled alone, dressed as a native. These and his other journeys were undertaken, not to satisfy a restless spirit, but to acquire knowledge at first hand. The result, so far as China was concerned, was that he knew the country better than did any Chinese statesman, for no one of these had studied it from as many angles. Little by little he came to be consulted as one who could speak with comprehensive knowledge, and he was frequently consulted, especially during the three critical years before the Boxer atrocities startled the world in 1900, and also during the anxious time just before the beginning of the Russo-Japanese War in 1904. The following year, at the Russo-Japanese Peace Conference at Portsmouth, no one among the one hundred and twenty newspaper correspondents awakened more sympathetic respect than did Dr. Morrison. The appointment of such a man is a significant sign of President Yuan Shi-kai's recognition of the fact that a young republic like China would do better with a tutor than without one. —*The Outlook*, September 14, 1912.

A Light Without Matches.—Every motorist has probably at some time been in the predicament, especially if a non-smoker, of being overtaken by darkness while on the road, without a single match. There is a simple method of obtaining a light, the knowledge of which may on occasion prove important. Unscrew one of the spark-plugs, and let it lie on the cylinder head. Wrap a small wisp of waste around the end of any stick, or tool, and soak it in gasoline. Lay this close to the spark-plug and turn the engine over until this plug sparks, when you will have a torch to light your lamps (and, in emergency, your cigar).

Piping Leaks Waste Acetylene.—It is no "pipe dream," but a reality, that over fifty per cent. of the cars using acetylene headlights have leaky pipe lines. Investigation has also shown that through these leaks more gas escapes than is burned in the lamps. The chief source of the leaks appears to be in the rubber tubing. In many cases this has been in use for many months, and through exposure to the weather and natural wear, cracks result. A few cases are found in which the brass pipe line has become chafed in spots, while in other instances leaks are found in the lamps themselves. Renewal of the rubber tubes semi-yearly and inspection of the metal pipes will often save the loss of many cubic feet of gas.—*Automobile Topics.*

GOUT OF THE INTESTINES.

By ALEXANDER HAIG, M.A. and M.D. Oxon., F.R.C.P.

CONSULTING PHYSICIAN TO THE METROPOLITAN HOSPITAL, SENIOR PHYSICIAN TO ROYAL WATERLOO HOSPITAL FOR CHILDREN AND WOMEN.

It is interesting to see that gout explains nearly all the "diseases" of this part of the body, and in the new light which it throws on their etiology and pathology we see clearly that these troubles are not and never have been diseases in the sense of definite pathological entities, but correctly speaking are mere incidents in the course of food poisoning by uric acid.

To follow an anatomical order, we shall here get a complete explanation of nasal and pharyngeal catarrh, catarrh of the neighboring larynx and trachea, catarrh of the esophagus of the stomach, gastroduodenal catarrh and jaundice, ulceration of stomach and duodenum, colitis, appendicitis, and some forms of piles. We shall also get a complete explanation of the immunity of the small intestine from these troubles.

This causation also explains completely the incidence of cancer of these same parts, as it is now seen to affect exactly the same parts as gout does and in the same order. This fact therefore clinches the relationship between gout and cancer and shows that if cancer is due to parasitic invasion its parasite is, like that of catarrh, influenza, tubercle, and malaria, unable to attack those individuals or those parts of the body which are free from the gout poison—uric acid.

And so we may note at the outset that these troubles affect just those parts of the alimentary tube which either are acid, owing to acid secretions, or are exposed to the introduction of acids in food, or to cold on the surface of the body, or to cold food (iced foods and drinks); while they as carefully avoid those parts which are alkaline and owing to alkaline secretions are less exposed to the bad effects of acids and cold.

The attempt to cover in the space of a single article so wide a field must be my excuse if my remarks about some of these conditions are very short, and if I take as granted and known what I have already said elsewhere.

Thus in the *British Medical Journal*, 1908, Vol. I, p. 1100, also "The Etiology, Prevention, and Treatment of a Common Cold," Bale, London, price 3d., and in "Uric Acid as a Factor in the Causation of Disease," Ed. VII, Ch. IX, I have shown that catarrh of the nose, pharynx, larynx, trachea, and bronchi, as seen in the course of a common cold, is a gout or rheumatism of these tissues which may be precipitated by cold or a microbe or by both acting together; that in treatment we do not require to trouble about the parasite in any way, provided we remove the uric acid by means of an alkali (pot. cit. or sodii bic.) and that those whose bodies have been cleared of excess of urates by several years on natural uric-acid-free foods are immune to catarrh in all forms, and to any of the parasites associated with it.

These people are similarly immune to gout of the intestines and are most unlikely to suffer from cancer in this or any other part.

But to return to our immediate subject, the nose, pharynx, and larynx are all exposed to the action of cold and of microbes, and if cold can precipitate upon these parts a few particles of urate this will give rise to the congestion which we call inflammation and in the irritated area the microbes can flourish and the process thus begun may then travel along these tubes by continuity from end to end.

This explains what takes place in an ordinary catarrh, and the vicious circle of this phase of food poisoning is at once cut through by means of an alkaline solvent which removes the urates; immunity is afterwards acquired by keeping them out by a diet which is free from poisons. This relation to alkali and alkalinity also explains for us why gastroduodenal catarrh may stop at the duodenum and why gastric congestion and ulceration are relieved by alkali (see later).

The esophagus is only occasionally affected by gout, which here generally takes the form of myalgia, causing pain as the bolus of food passes down over the seat of irritation. This may be an incident in a catarrh descending from the pharynx, or may be produced by the action of certain hot, acid or otherwise irritating foods. The esophagus is but little exposed to cold as compared with the pharynx, for instance, hence gout of the esophagus is less common than that of the parts above it.

According to Mr. Roger Williams, "The Natural History of Cancer," London—William Heinemann, p. 380—the tongue and mouth are much more affected by epithelioma than the esophagus, but the esophagus suffers more than the intestines apart from the stomach and rectum, the two latter being, as I remark, the most acid parts of the alimentary canal.

Catarrh of the stomach and duodenum is liable to be set up in the food poisoned by several things such as descent of catarrh by continuity from above, the local action of cold, the local action of acids, corrosive and irritating substances in the food, and under certain abnormal conditions by the excessive action of its own secretion. Thus the epigastrium is often exposed to cold, *e.g.* when the clothing in front of the body is unfastened or diminished while cycling or motoring against the wind, then precipitation of urate (gout) may take place in a moment and the rest follows. Once you have set up a local precipitation the process goes on of itself. Ices or iced drinks, or acid foods or drinks may act in the same way and start a process which will go on of itself long after the cause has been forgotten.

This etiology explains also a point noted by Mr. Mansell Moullin in his paper on "The Significance of the Symptoms in Cases of Duodenal Ulcer," *Lancet*, 1912, Vol. I, p. 566, namely, that the trouble returns again and again in the same part of the stomach or duodenum. The explanation is exactly the same as that of the formation of a gouty tophus in the toe, once some urate has been thrown out there, it attracts more and more till there is a lump as large as an egg. In the same way the urate in the wall of the duodenum not having been completely cleared out after the first attack of gouty irritation, more is easily attracted to the same spot whenever the blood is full of it, or when cold, acids, or some slight alteration in the digestive process increase the local acidity and congestion. Thus trouble of this nature may go on either in the stomach or duodneum more or less intermittently for days, weeks, months, or years, till the patient from long illness becomes debilitated and collemic, or till the stage of life alters, or till some one gives sufficient solvent to clear out all the urate from the gastric or intestinal wall, or till food poisoning is put an end to by ceasing to swallow xanthin. I have seen numbers of cases where patients have suffered for fifteen or twenty years from such gastric or intestinal irritation, gastritis, gastralgia, heartburn, etc., simply because no one had given a solvent of uric acid, or not in sufficient quantity or sufficiently long continued; where a solvent has at once relieved and a change of diet has then kept them free from all further trouble of this nature. It is indeed small wonder if many years of such constant or recurrent irritation frequently pave the way for cancer, and we here see clearly one way in which change of diet may prevent this deadly sequel.

The causation of gastrointestinal dyspepsia, defective secretions, deficient bile secretion is thus quite easily explainable, for these symptoms are obvious results of congestion and catarrh of certain portions of the alimentary tract. Several of these signs together with bilious attacks, migraine, and vomiting are obviously mere incidents in the course of chronic food poisoning affecting at one time chiefly the circulation and, causing high blood pressure, migraine, eye symptoms, retinal changes, at another chiefly the local tissues, causing catarrh, dyspepsia, altered gastric and duodenal secretions, with more or less marked failure in the digestion and metabolism of food.

In regard to the treatment of such a case my rule is that every chronic or recurrent gastric or duodenal pain may be a gout of the part if (1) it comes in a retentive stage of life, (2) if the patient has signs of uratic irritation elsewhere, especially in the joints, (3) if it comes in relation to excessive gastric acidity, and (4) if it is made worse by local cold or by acids (wine, fruit, etc.) in the food. Then if my diagnosis is correct it will be promptly relieved by solvents and infallibly cured by the uric-acid-free diet.

With reference to gastric and duodenal ulceration, Mr. Mansell Moullin clearly shows in the above-named article (p. 565) that the primary cause is chronic and recurrent local congestion which leads sooner or later to a rupture of the surface with removal of its epithelial coat and then the acid gastric juice does the rest. He considers that the pain is due to muscular spasm of the congested part (colic of the stomach, pylorus, or duodenum), though if the congestion goes on and leads to ulceration this will increase the pain. He also considers that hemorrhage is often due to bleeding from a congested surface, and, except when it is copious, is not to be regarded as a sign of ulceration.

No doubt there is a further cause of gastric or duodenal ulceration in embolism or thrombosis, which by producing local congestion, resembling that caused by gouty irritation, leads up to a break in the epithelium and so to local digestion. But there is no more frequent cause of embolism than endocarditis or of thrombosis than the effects of uric acid on the blood and its circulation, so that here again we have to deal with nothing but food poisoning and its primary and secondary effects. We must also bear in mind that any irritation, however it originated, is liable to be kept up in the urate laden by the precipitation and reprecipitation of urates in the acid and irritated parts. For the more a tissue is irritated and inflamed the more acid it becomes and the more completely will all the urate in the blood be attracted to it and deposited within or upon it. There is no end to such a process except the end of the urate supply, or a change in the stage of life which substitutes a collemic or solvent stage for a retentive one, and this not in one place only but throughout the whole body. (See "Uric Acid," p. 236.) This is the way that alkalies act in relieving those gastric and duodenal troubles, and in all tissues affected by uratic catarrh; it is not a mere matter of the neutralization of acid gastric juice, but the blood everywhere is rendered a good solvent of urates and tends to take them up from the tissues in place of throwing them out; and with their removal the local irritation, by whatever name we have called it, subsides. Hence, as I have pointed out in the case of bronchial catarrh, we must give sufficient alkali and continue it sufficiently long to greatly increase the alkalinity of the blood and to diminish often to nil the acidity of the urine, and it is by failing to do this that many fail to get complete and conclusive results.

We need not now say very much about the relative immunity of the rest of the small intestine, it is a simple result of its alkaline contents and secretions. But this immunity is relative only, for if anything overcomes its alkalinity, *e. g.* acids in the food, or produced by fermentation, or if it is acted upon by such metals as lead or mercury which precipitate urates into its tissues, we may get gout even here and it is likely to take the form of colic, *i. e.* muscular spasm, as this is the first reaction of such intestinal tissues to the irritation produced by urate compounds with the metals, and flatulence is the sign of a minor stage of the same form of irritation. Such flatulence and colic can always be relieved by a sufficient supply of a solvent to reverse the process and take up the urate into the blood stream.

We may now pass on to the large intestines where the reaction of the canal and of its contents again become acid and where we should expect just what we find, that the structures in its walls are again liable to acute and chronic catarrhal processes, due, as before, to the local action of acids or of cold or any irritating substance which may originate local uratic precipitation and thus start a process which will continue of itself.

Such is the origin of a gouty catarrh, which here again may spread throughout the whole of the large bowel, or after an acute blaze up may become chiefly local in one part of it, just as after an acute and general arthritis one or two joints may remain

seats of chronic local and recurring irritation. This similarity of course and duration also means identity of causation. Such a catarrh may become chronic, associated for weeks, months, and years with the passage of more or less large quantities of mucus, it may remain more or less general over the whole tube or become chronic in certain regions, *e.g.* the cecum and appendix or the sigmoid flexures, where it may ultimately give rise to thickening, adhesions, distortions, associated with most obstinate constipation, or may go on to more or less severe local ulceration, perhaps as in the case of the appendix ending in perforation. The obvious clinical relation of many cases of appendicitis to gout is thus easily and completely explained.

Then again some forms of piles are quite clearly related to exposure to cold, as for instance by sitting on cold stones or on damp ground, or to the taking of acid fruit or of fruit out of season, or of fruit which comes from a warm climate but is consumed in a cold one, and if any of these things acting apart or together sets up a gout of the fibrous tissues of the lower rectum or anus we get a local general or venous congestion essentially similar to those described above and curable in the same way by a recognition of the fact that solution and removal of urates is the effect we must produce. Any of these causes acting singly or in combination might equally have affected some other portion of the intestinal tract, but just as they fail to affect the small intestines below the duodenum, so will they be most likely to act on any part of the intestine which is most acid or is at the time most subjected to irritation from the nature of its contents or surroundings.

Any application of cold to the abdomen or lower extremities is always dangerous for the urate-laden. But those who have taken the trouble to get moderately free from these poisons have more or less decided immunity up to absolute freedom, and this freedom is, practically speaking, a measure of the amount of urate they still have in their blood and tissues. On the other hand prolonged exposure to cold may eventually produce trouble in any one, however free from urate their diet may be, for the effect of exposure to cold for a week or ten days is to accumulate a store of urate in the liver, spleen, or elsewhere in the body, and those who have a store have lost their freedom and are, to the extent of their store, as liable to uratic catarrh as those who feed wrongly; and this catarrh will affect any seat of local irritation, either the part exposed to cold or any other part of the intestine, or of the body whose alkalinity is for a time diminished. Thus it may affect the seat of old uratosis, adhesion, ulceration, etc., or a new part which has been exposed to severe cold, irritation, or injury.

As we see in "Uric Acid," (*loc. cit.*, p. 432), sprue is an intestinal trouble sometimes related to exposure to cold. People go to sleep in warm climates only lightly covered and perhaps do not wake in the morning till they are chilled and cold owing to a great change of temperature. In this way there may originate in the food-poisoned a gout of the intestines which is called spruce or "hill diarrhea." This is in many cases quite successfully treated by solvents, and may be cured, like other catarrhs, by the uric-acid-free diet; but, apart from these, it is liable to be repeated and eventually to become chronic and almost incurable. So far as I can judge, its primary symptoms seem to be those of catarrh and catarrh anywhere in the body is gout.

Thus it happens that I have cured some cases of sprue which had come home to die, simply by making them uric acid free; no catarrh can survive that. Most of the symptoms of sprue, viz., diarrhea, undigested food, especially undigested fat, and absence of normal bile coloring matter, are common incidents of duodenal congestion and catarrh as seen in this country. Some consider sprue to be related to dysentery and this again is but a gout of the intestines, it does not attack the uric acid free and many cases are cured by the uric-acid-free diet. The common treatment of sprue by warmth and milk diet is testimony to the same effect. Ipecacuanha, again, a specific for dysentery, has a good effect on catarrh in every part of the body, and the relation of colitis, colonic catarrh, and dysentery to starvation is again very easily explained if we regard them all as gout of the intestines. Here, also, just as in catarrh of the respiratory tubes, microbic invasion may play a more or less important part in causation, but as a rule I believe we need waste no time on the microbes if we first dissolve out the urates and then keep the patient uric acid free for years.

What is true of sprue apparently applies equally to acute summer diarrhea of children in this country, for this also is in many cases a catarrhal process and catarrh everywhere is gout. Coming as it does in our hot season, or as the hot season merges into autumn, the conditions present, namely hot days and cold nights, resemble to a remarkable extent those that give rise to sprue.

All the wrongly fed children in this country are full of uric acid, and the hot weather brings this into the blood in large quantity. On this there follows a chill of the abdomen owing to a restless child kicking off the bed clothes and the result is a gouty or catarrhal enteritis with vomiting, diarrhea, and rise of temperature.

Here, just as in the similar catarrh of the bronchi, you have only to give enough alkali (at least 20 gr. every two hours) to get the urine quickly alkaline, and the temperature falls within forty-eight hours and the vomiting and diarrhea cease.

Alkalies have often been used in summer diarrhea, but never, so far as I know, in a dose comparable to that which cures bronchitis, and ipecacuanha has been found useful in it just as in the other similar troubles mentioned above.

If the treatment by alkali were to be widely used we should soon see how much of our summer diarrhea was due to gout and gout only, just as we now know that all bronchitis which is not part of a specific disease is not dangerous, as it can be quickly cured by alkali.

In summer diarrhea the alkali does best when given alone, even bismuth is a hindrance to its action rather than a help, but where the diarrhea has led to collapse you have to deal with a heart which is feeble and dilated from defective nutrition, and then the alkali may be combined with small doses of strophanthus or digalen; but ammonia and all stimulants which are also retentives of uric acid are, just as in the case of bronchitis, out of place. It is much more important to put an end to the inflammation than to stimulate.

And just as it is now clear that catarrh spreads through the respiratory passages and other portions of the body owing to the fact that microbes flourish in urate-laden tissues and as there is at least considerable suspicion that similar conditions favor the spread of tubercle (see "Uric Acid," *loc. cit.*, p.

394) why may not cancer also do the same in the same way, tissues irritated by urate deposits and accumulating waste products favoring its spread? Indeed owing to the researches of Mr. H. C. Ross we now know that some waste products closely related to uric acid excite cell proliferation and tumor formation. (See "Induced Cell Reproduction and Cancer," by H. C. Ross, London. John Murray, and "Further Researches into Induced Cell Reproduction and Cancer," by H. C. Ross and others, 1912.)

The effects of correct diet are probably twofold, for not only are urate-laden tissues with defective circulation and deficient removal of waste products favorable breeding grounds for many kinds of microbes as well as for endo- and ectoparasites, but tissues which are free from urates and waste products and have a natural quick capillary circulation are most unfavorable for them.

Syphilis again may furnish another instance of a parasitic organism profiting by the conditions brought about by uric acid poisoning in tissues and their circulation. The effect of mercury as well as of iodides is to clear the blood of uric acid and to free the circulation from its lethargic grip, hence it produces conditions unfavorable to the parasite, and not to this one parasite only but to many. And here we come into position to understand the cure of syphilis by diet without drugs, for the uric-acid-free diet produces the same effect on the circulation that mercury does, only the effect is permanent in place of temporary. (See "The Schroth Cure," by Dr. S. Moller of Dresden. London: George Standring, pp. 37 and 66.) This diet relationship may explain why syphilis was less prevalent in olden times when there was less flesh eating, and there was no tea drinking in Europe till the sixteenth century. Thus I note that Dr. Norman Moore said in the recent debate on syphilis in the Royal Society of Medicine (*British Medical Journal*, 1912, Vol. I, p. 1426) that syphilis was unknown in Europe till the end of the fifteenth century. When writing about the Schroth cure a few years ago I did so under the name "Hunger and Thirst Cure," for patients may object to admit that they have been through the Schroth cure owing to its use for specific disease.

It is not needful to do more than point out that cancer affects just the same parts that gout attacks and avoids other parts, *e. g.* the small intestine, with suggestive regularity. Catarrh in the nose and pharynx leads to the formation of polypi and these may become cancerous. Cancer may also affect the nose and eyes and the parts near them, parts also affected by catarrh. Mr. Roger Williams (*loc. cit.*, p. 385), says, "The great predisposition of the skin of the face, especially that of the nose and its vicinity, to develop cancer is remarkable." It is remarkable that cancer attacks the stomach and duodenum and the parts adjacent such as the liver, gall-bladder, and pancreas, and then we have again considerable immunity for the small intestine which diminishes decidedly in the large intestine, especially as we pass to the left of the middle line and its contents become more concentrated and more acid. It is also remarkable that the small intestine has considerable immunity from non-malignant tumors, such as fibromata, myomata, papillomata, and polypi; and we have already known for a long time that fibromata of the uterus are related to gout. ("Uric Acid," p. 715.) It is also probable that these non-malignant tumors are, owing to the chronic irritation which they tend to keep up and intensify, frequent starting points of malignant growths.

Mr. Roger Williams (*loc. cit.*, p. 381) says that tongue, mouth, face, and lips account for about 9-10 per cent. of cancer cases, and on p. 384 he notes after speaking of the great preponderance (61 per cent.) of intestinal cancer in the rectum, that only 5 per cent. is found in the great length of small intestine and that the duodenum is rarely affected.

It is hardly likely that so large a number of facts and so complete a parallelism, involving gout, non-malignant and malignant tumors, can be explained by anything short of identity of causation. Thus the local natural history of cancer and its incidence in the intestines emphasizes what the diet history of the world shows, that gout and cancer go everywhere together hand in hand, being both of them less common in warm and more common in cold climates, because they are but two results of one and the same cause—local irritation by food poisons.

Among minor points which my knowledge now enables me to explain quite easily, I may mention Mr. Mansell Moullin's observation (*Lancet*, 1910, Vol. II, p. 995) that an operation has a great effect in relieving or curing local gastric or intestinal congestion. He attributes this largely to the fact that the operation lowers blood pressure and this may explain it (see "Uric Acid," pp. 625-6), but I may add that if the patient and his nutrition are considerably upset by the operation there will come, two or three days after the operation, a marked fall of urea and acidity, and such fall of acidity is practically equivalent to a course of alkali, the action of which I have already spoken of.

He also points out (*Lancet*, 1912, Vol. I, p. 563, and *Lancet*, 1910, Vol. II, p. 996) "The Essential Cause of Gastric and Duodenal Ulcer," that duodenal ulcer is considerably more common after thirty in males than in females, but this is easy to explain if we are dealing with a gout of the intestine, for thirty is in the second or great retentive stage of life ("Uric Acid," *l. c.*) and retention is always more marked at that age in males than in females, as the latter excrete excess of uric acid at each monthly period and as a result of this suffer comparatively little from gout till after the menopause.

Mr. Mansell Moullin also remarks that pain is worse after meals and especially at night, but so is the pain of gout in any other part, for after meals, and especially at night, there is a rise of acidity. The effect of food is at first to increase alkalinity, during which stage it may do good. But this effect does not last long as its later effect is to cause a rise of acidity and do harm. He also refers (p. 564) to the notion that alkalies relieve merely by diminishing the acidity of the gastric juice; but I quite agree with him that this is not a complete explanation of their action and that here, as in bronchial catarrh and other uratic irritation, they relieve by dissolving uric acid and removing it from the irritated tissues.

As he also points out (*Lancet*, 1910, p. 997), strong acid may be put into the stomach or it may be cauterized without producing any pain, so that it would require something much stronger than normal gastric juice to produce pain. His conclusion, with which I quite agree, is that the pain is due to local congestion complicated by muscular spasm, and this, as we now see, is a common result of urate irritation both in the stomach, intestines, and the uterus.

He looks upon colic as painful spasms of muscle due to local irritation, and this is no doubt the way in which lead, mercury, copper, tin, and other metals produce colic through uratosis; and flatulence, as I have long known, is but a minor condition of the same thing. Any exposure to cold, acid fruit, acid wine, or cider may in the urate-laden produce first flatulence and then colic, and what relieves the one relieves the other. On p. 566 he speaks of the curative effects of alkalies and starvation; and starvation is equivalent to a course of alkali, the effect of which it increases. An exactly similar treatment by alkali and starvation is most useful in the case of ordinary bronchial catarrh.

Mr. Mansell Moullin also lays much stress on the effects of septic poisons swallowed from the mouth when teeth and gums are in a bad state. But these have little effect either on the stomach or the joints when swallowed by the uric acid free, though to be uric acid free always diminishes to a considerable extent the tendency to such things as Riggs' disease, dental periostitis and other local uratic troubles, the Riggs' disease thus proving itself to be but one further instance of the combined action of microbes and urates.

The relation of duodenal ulcer to burns is attributed by Mr. Mansell Moullin to septic absorption, but any shock to the body of a gouty man is a potent cause of gastroduodenal congestion from collemia, and an interesting case he mentions (p. 566), that of a young man who got jaundice following slight traumatic synovitis or other injury, could, as he notes, hardly be due to sepsis, but is easily explained by shock inducing collemia and circulatory congestion in the stomach, liver, and duodenum. This young man was probably in the first collemic stage of life and therefore specially likely to be affected in this way; a few years later he will cease to be so easily affected. Mr. Mansell Moullin says we are still very ignorant regarding the vascular and nervous supply of these regions, and as regards the circulation I quite agree—we have still much to learn.

He also refers to the way in which what appears to be a trivial exposure to cold will cause a relapse of all symptoms after perhaps a considerable period of immunity, and this is, as I know, quite true for the food poisoned, but not for the uric acid free.

So far as I know there is no necessary limitation of gout to any one layer of the intestinal walls; urates may be precipitated in any layer at any moment and continue to affect that layer or spread either inwards or outwards to neighboring layers, according to the amount of urate available and the local conditions affecting either its precipitation from or its resolution in the blood stream. There is no condition tending more strongly to local precipitation than the presence of urates already in the tissue, and it is by aiding solution and removing all previous deposits that alkalies cure. But cure is only complete when removal is complete.

The frequently observed relation of all such processes to gout and rheumatism is thus easily and completely explained, and the relationship is so frequently met with that some have been even inclined to look upon gout as a gastrointestinal toxemia; but I am sure that this is an inverted reading, catarrh and uratosis are the first step after an excess of uric acid has been poured into the body by unsuitable food, and then catarrh and uratosis lead on to chronic dyspepsia and so to debility, anemia, neuroses, and neurasthenia, some of which are thus but mere stages in the course of food poisoning.

Whether all new growths and cancers originate in seats of such chronic local irritation has still to be found out, but it is certain that many do so.

I regard local treatments and intestinal antiseptics and irrigations as of little use. The first thing to do is to get the blood into a condition to dissolve out the urates, and this also is the effect of heat, which is both directly and indirectly a solvent of uric acid. For the same cause foods that cause local irritation can have but little effect so long as the blood is in a condition to dissolve and take up urates in place of throwing them out. Probably the local effect of many irritants is small, but great harm is done when that effect is constantly increased and kept up by uratosis. In this way the seat of a recent fracture in a bone may give its urate-laden owner some six or eight distinct periods of irritation in the course of the twelve months of changing seasons; but if he becomes uric acid free these gradually cease to trouble, so that after a year or two he may quite forget where the fracture was. It is exactly the same in the case of the viscera of which we are speaking, comparatively slight irritation or exposure to cold may start trouble when there is plenty of urate available.

I myself in my food-poisoned period certainly suffered from "hunger pain" and used to carry biscuits to bed with me. I doubt whether I ever had gastric or duodenal ulceration, but I often had congestion and colicky contraction of muscles (the cause of the pain) due to a local uratosis (gout). But such sensations are now memories only; they disappeared years ago along with the other symptoms of a food poisoning which has long ceased, but which could, I believe, be easily reproduced by a further dose of poison. It was often thought that I suffered from gallstone when I was a boy, but the diagnosis was held to be inadmissible on account of my age (early twenties). What I really had was colic of certain areas in the stomach and duodenum due to uratosis, and 5j of sodii bicarb. in 10-15 oz. of warm water promptly relieved.

Salicylates act in exactly the same way by dissolving out and removing the urates which cause the irritation; but certain conditions, viz., good strength and nutrition, fever, highly acid food, favor the solvent action of salicylates, while the opposite conditions, viz., debility, starvation, subnormal temperature, favor the action of alkalies. It matters very little which you give, but give those which are favored by the general conditions present in the given case. Then in all cases which are thus relieved by solvents the uric-acid-free diet will finally prevent and cure, and if, as seems probable, a diet poor in protein aids recovery from cancer, it here acts in just the same way as it does in the parallel conditions of gout and catarrh.

In the light of these facts we can see that bread not only constipates by the action of the astringent salts it may contain, but that by the acidity of the wheat, the added acids of baking powders, and of fermentation it is a cause of gout not only in the joints but in the intestinal canal, and thus aids in the production of chronic catarrh, fibrosis, and adhesions and the eventual conversion of a functional constipation into an organic. Even apart from the xanthin which its fibrous coverings contain, wheat is not and never has been a natural food for man, and the only individuals of the species who show any evidence of being able to thrive upon it are those who, living laborious lives, excrete day by day from their skin glands considerable quantities of the acid it supplies.

The causation of uterine fibroids, as also of fibroids and fibrosis elsewhere, is very often a mere matter of recurrent monthly irritation by gout. The first stages of the process are accompanied by pain of a colicky nature, which tends to appear just as the postmenstrual collemia is coming to an end and retention takes its place. Such pain may be met with from about the fifth to the tenth day after the cessation of the period, and the uterine and intestinal fibrous tissues are the parts in which the urates are retained. (See "Uric Acid," p. 153, *et seq.*)

Underfeeding, starvation, or the hunger and thirst (Schroth) cure may relight an old or smouldering colitis, just as a single day of hunger or the dropping out of a meal or two may relight an old pharyngitis or tonsillitis by getting some old urate deposits into solution; for it is urate in solution which causes the irritation and not the biurate deposit, which is often seen in the tissues without a sign of recent inflammation round it. A course of alkali, which acts in the same way as hunger or starvation, may also make things worse at first by getting some old deposits into solution, but continue to give it plentifully, and, with the complete removal of the urate, the trouble will gradually subside, and then a precisely similar course of alkali given a few weeks or months later will not light up any trouble as all the urates are gone.

As the urate is being got into solution it may not only cause local iritation, it may be redissolved and reprecipitated in other distant parts, even to the extent of bringing out the picture of acute rheumatism, a sequence which is specially likely to be met with in dealing with the large quantities of urate sometimes present in the body and blood in Bright's disease, for instance.

Hence in those who have once had a colitis, even perhaps years previously and entirely forgotten, hunger or starvation or a change of food to something that is more alkaline than usual (*e.* g. potato), may suffice to light up a colitis once more, but continue the solvent process, and when all the urate has been dissolved out and excreted the local irritation will subside, and, if the body is now kept clear of urate excess, need never be relighted. These symptoms and phenomena are all matters of urate solubility under constantly varying conditions of food, climate, drugs, and time of life.

We see then that gout of the intestines is a catarrhal process, affecting first of all the mucous coats of the alimentary canal. It may be limited to the mucous coat or spread to neighboring fibrous tissues. It goes through various stages of congestion, with mucous, mucopurulent, and purulent exudation, and is more easily cured in its early stages before the exudations are purulent. It may go on to ulceration, fibrous tissue increase, adhesion, and distortion of structure, more rarely to definite accumulation and deposit of urate in bulk (biurate) visible to the naked eye; but a certain amount of interstitial accumulation to be found by chemical analysis is not uncommon. It affects chiefly and in the first place parts exposed to cold, acids, heat, or irritant substances. It may spread from these parts either by fibrous tissue continuity or by the spread of microbic invasion hand in hand with urate precipitation and defective circulation and metabolism through the tissues.

The chronic irritation it produces in these tissues may, like the similar irritation similarly produced in other tissues, though called by other names, pave the way for cancer, and cancer, like the catarrh which precedes it, affects, as we now see, chiefly the parts exposed to cold, acids, heat, and irritant substances. Both cancer and catarrh avoid those parts which are not so exposed, or which owing to warm position, alkaline secretion, and a large supply of alkaline blood are but little liable to urate precipitation. They both also affect largely the acid parts, stomach, and rectum.

These intestinal troubles not only occur in constant relation to gout and rheumatism in other tissues, but in common with bronchial and other respiratory catarrhs are all made worse by acids, cold, and retentives, and all made better by alkalies, heat, and solvents of uric acid, so that the diagnosis in any given case need not long remain in doubt.

And once this diagnosis has been correctly made it is a matter of certainty that the uric-acid-free diet, properly inaugurated and continued, will remove eventually not only all signs of and all tendency to catarrh but many even of the fibrous tissue changes and distortions. We thus get an explanation of the fact that some parts of the intestines are specially liable to both gout and cancer and can see that a similar explanation may be given of the spread and special tissue habitats of tubercle and syphilis, so that in fact, as I have said before ("The Circulation as a Factor Which Determines the Effects of Microbic Invasion," MEDICAL RECORD, September, 1910), if a man is free from food poisoning he is practically free also from the more serious forms of microbic and parasitic invasion.

AGAR TUBES FOR THE ESTIMATION OF THE PANCREATIC FERMENTS.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

THE accessibility of the duodenal contents including pancreatic juice for examination has created a more frequent demand for the analysis of the pancreatic secretion.

Besides testing it for reaction whether neutral, acid, or alkaline, specific gravity, appearance, and admixture of mucus, the principal point of importance is to ascertain the presence or absence of its three ferments: amylopsin, steapsin, and trypsin, and if possible their approximate amount. The usual methods serving this purpose are somewhat complicated. It has appeared to me that if the tests were simpler the examination of the pancreatic function would be more often undertaken by the clinician, and in this way be of more assistance in diagnosis.

My aim was at first to make use of Mett's tubes for the determination of the trypsin ferment and to arrange for similar tests for the remaining ferments. Mett's tubes proved unsatisfactory for this kind of work, the albumin frequently failing to disappear, notwithstanding the presence of trypsin. Fermi's gelatine tubes which I used in conjunction with Rosenbloom are much more appropriate, the only disadvantage being that they have to be kept at the temperature of the room. In as far as the tests for steapsin and amylopsin are better made at blood temperature, it requires separate specimens, some to be kept at the room temperature and others at blood temperature. In dealing with small quan-

*Read before the American Gastroenterological Association on June 3, 1912, at Atlantic City, N. J.

tities of secretion, as is often the case, this is a drawback.

For amylopsin starch-tubes have been used by Wohlgemuth. My attempts to employ the same kind of tubes for the amylopsin tests failed utterly. If we took a high percentage of starch, 8 to 10 per cent., in the tubes, it would not liquify, but would remain as a solid mass in the tube, while on using a lower percentage (5 per cent.) it would flow out completely without the presence of the amylopsin.

These tubes not working satisfactorily, it occurred to me to use test substances in agar vehicles. The principle is the following: Agar tubes,—mixed with albumin, starch, fat,—allow the ferment action to take place in them by osmosis. If the test substances added are colored with indicators, which undergo a change when acted upon, it is easy to ascertain the presence of the ferments, and also to estimate their approximate amount by the volume of tube changed given in mm.

The manner of making the different kinds of tubes is as follows:

I. Starch Tubes.—Agar powder, 2.5; starch, 5.0; tincture of iodine (U.S.P.), 2.0; distilled water to make, 100.0.

Rub the starch and agar in a mortar with sufficient water to make a smooth paste, add the tincture of iodine and then the balance of the water. This mixture is placed in a flask and heated to the boiling point. It is then drawn by suction into a capillary glass tube (inside diameter one and one-half millimeters) which has previously been warmed in the flame. The tube and contents are allowed to cool and are then cut into three centimeter lengths. These are sealed at each end with melted paraffin.

II. Olive Oil Tubes.—Olive oil, 1.0; agar powder, 2.5; phenolphthalein test solution (U.S.P.), 1.0; potassium hydroxide test solution (U.S.P.), 0.5; distilled water to make, 100.0.

Rub the olive oil and agar together, add sufficient water to make a thin paste, then add the test solution and finally the balance of the water. Proceed then the same as with starch tubes.

*III. Hemoglobin Tubes.**—Hemoglobin powder, 1.0; agar powder, 2.5; distilled water to make, 100.0.

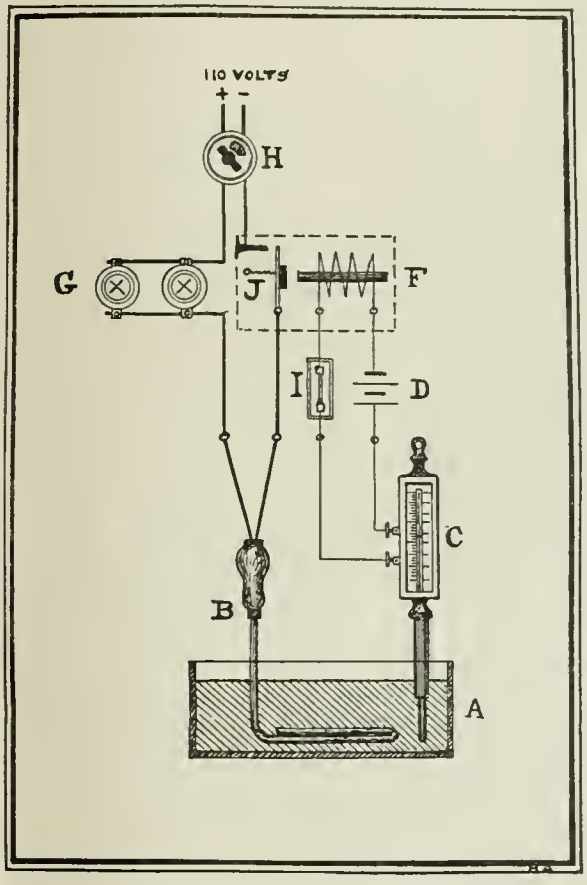
Rub the hemoglobin with about 10 c.c. of water until it is smooth, add the agar powder and the balance of the water; then proceed in the same manner as with the starch tubes.

When these tubes are acted upon by the ferments the dark blue starch tube, the red olive oil tube, and the brownish hemoglobin tubes will all be discolored, beginning from the end of the column touching the fluid for quite a distance upward, generally depending upon the amount of ferments present.

While in our first experiments the control tests with boiled specimens showed no changes, later on we noticed that these also, particularly the starch and olive oil tubes, became discolored sometimes to a considerable extent. This circumstance threatened to spoil the entire method. The cause of the discoloration in the boiled specimen cannot be the action of the ferment, as the latter has been destroyed. It is simply due to a disappearance of the coloring matter (iodine in the starch and phenolphthalein red in the oil) through osmosis, while the test substances themselves have in reality undergone no change, *i.e.* the starch still exists as starch and the olive oil likewise as neutral oil.

In the unboiled specimen, however, the discoloration brought about is due to an intrinsic change of the test substances; the starch has changed into sugar and the neutral olive oil has been split into fatty acids and glycerin.

This differentiation can be easily demonstrated by pushing out the agar columns from the glass tubes and dipping them—the starch ones—into a weak iodine solution, and the olive oil ones into a weak phenolphthalein alkaline water solution. The unboiled specimens will show that the starch agar



ABRAHAM'S ELECTRIC THERMOSTAT.

A represents a vessel filled with water containing a heating coil, B, and a Fahrenheit thermometer, C, having one platinum wire fused in the glass stem at the 100 degree division, and another platinum wire fused in the bulb. The thermometer is in circuit with the dry batteries, D, and a 75 ohm telegraphic relay, F. The heating coil is in series with the incandescent light bulbs, G, and the relay, F. The switch, H, controls the main circuit, illustrated by the heavy lines, and the switch, I, the battery circuit, illustrated by the light lines. When the mercury in the thermometer rises to the 100° mark, it makes contact with the platinum wire fused in the stem and closes the battery circuit which operates the relay, F. This interrupts the main circuit and shuts off the current from the heating coil, B. As the bath of liquid cools, the mercury in the thermometer, C, falls until the contact is broken. This shuts off the battery current from the relay, and again allows the main circuit to be closed by the action of the spring, J, which actuates the armature of the relay.

column does not turn blue, provided amylopsin was present, and that the olive oil agar tubes do not assume the pinkish red color. They retain the discoloration, while the boiled specimen stains in these solutions.

Method of Procedure.—Take one each of the starch, oil, and hemoglobin tubes, scrape off the paraffin at one end, tie them together with a piece of cord and put them vertically into a bottle containing the duodenal secretion. The latter is usually slightly alkaline, if not it should be made so by adding a few drops of sodium hydrate solution. Add a few drops of toluol and keep the bottle at

*I am indebted to Mr. Herbert Abraham, chemist of the Standard Paint Co., for suggesting the use of hemoglobin for the above purpose, and to Mr. John Seitz of Elmer & Amend for making the agar tubes for me.

blood temperature and corked for sixteen to twenty-two hours. It is best to make also the same test with boiled duodenal contents, in such a way that a comparison between the two specimens could be undertaken. The examination is made in the following way: the agar tubes are taken out from the bottle, wiped off, and inspected. The amount of discoloration in each tube is noted. The starch and oil tubes are further examined by pushing out the agar columns from the glass and dipping the one (starch) into a weak iodine solution and the other (olive oil) into a weak alkaline phenolphthalein solution. The portions remaining colorless indicate the amount of the ferments.

As a thermostat I use an electric automatic apparatus devised by Mr. Herbert Abraham.* The accompanying diagram shows the details of the electrical thermostat which is used for maintaining the water bath at a constant temperature of 100° F.

The above electrical thermostat of Abraham does not occupy too much space and is easily handled. It is particularly useful to practitioners who have no complete laboratory at their disposal.

The steapsin test with the olive oil phenolphthalein tube has the drawback that the juice must be made alakaline, for otherwise the same reaction will take place without steapsin. I have, therefore, been looking for another method which would bring on a color change due to the splitting of fatty acids and not be affected by other acids. Chlorophyl olive oil did not materialize, nor did Sudan red (III) olive oil agar tubes act in the desired manner. I have to investigate this matter more thoroughly. The hemoglobin tubes work very well, but are not sensitive enough, and it would be desirable to arrange for some improvement here also. I tried recently to have the hemoglobin tubes in two per cent. agar instead of two and one-half, which seems to do better.

The method of testing the ferments with the agar tubes seems to me to be simple and worthy of recommendation, although some details will have to be worked out a little further.

20 East Sixty-third Street.

HISTORY OF THE LITHOTOMY OPERATION.

By MAX KAHN, M.A., M.D., Ph.D.

NEW YORK.

DIRECTOR BETH ISRAEL HOSPITAL CHEMICAL LABORATORY.

(From the Department of Biological Chemistry of Columbia University, College of Physicians and Surgeons.)

While the history of medicine has been fully written upon by various European authors, the antiquities of surgery have not been much dwelt upon. In ancient days, when it was considered plebeian on the part of a physician to perform surgical operations, there of necessity developed a special guild of craftsmen whose business it was to treat undignified diseases for which the learned doctors refused to prescribe. These empirics, the barber-surgeons and charlatans of yore, untrained in learned conversation, unacquainted with the writings of the philosophers, attained great skill in their practice. Empiricism is ever the beginning of true science. In the history of surgery there is no more interesting chapter than the story of these chirurgeons.

Especially undignified was it deemed to perform lithotomy. Cutters for the stone were considered as altogether below the notice of the worthy doctors. Rated on a level with the undertakers and embalmers, they pursued their unhonored profession, and, though lacking in dignity and lucre, they perfected their art and did much to alleviate human suffering. The history of medicine in particular, like the history of humanity in general, is but the story of pain and suffering. There is no more painful disease than kidney or bladder stone, and it is no wonder, then, that in all nations we find mention of methods, old and new, for the improvement of stone cutting.

A surgeon was usually a lithotomist. When the ancients praised a surgeon they indirectly contributed toward the fame of the cutter for the stone. In the Persian *Vandidad,* or Book of Law, there is great praise for a certain physician who was also a surgeon: "Thrita was the first man of the race of Paradhata, helpful, discerning, powerful, rich, intellectual, to combat sickness and death. Ahura-Mazda, in answer to his prayer, caused countless healing herbs to grow, and gave him a metal operating knife."

In an old Hindoo papyrus we find particular directions how to perform lithotomy. They used the lateral section: "The hand being put on the abdomen and the stone being shoved down, the physician introduces the index and middle fingers of the left hand, the nails being cut, into the rectum of the patient, until he feels the stone. He then brings it between the anus and the urethra and presses on it till it stands out like a knot. Then follows the incision with the knife on the left side, the breadth of a grain of wheat from the raphe; under certain circumstances also on the right side, according to the size of the stone."

The Chinese with their more than Oriental imaginative powers, treated urinary diseases with horrible concoctions. They had peculiar ideas of therapeutics. "The red blossom of the hibiscus is employed as an emmenagogue; saffron, on account of its yellow color, in jaundice; and beans, for their shape, in kidney disease." The instruments that they used were so crude and their manipulations so lacking in dexterity, that they did not make much progress in practical medicine.

It is interesting to note that the Aztecs, whose civilization seems to have had no connection with that of the Asiatic or European nations, developed a medical science which peculiarly resembled the practitioners' art in Egypt and in Persia. Though they practiced theurgy more than they did surgery or pharmacology, still they made remarkable strides in the use of surgical instruments. Lacking iron, they fashioned their knives from obsidian. They opened abscesses by the crucial incision, and they scarified edematous swellings. They also used clean horse and human hair for suturing.

The Bible gives explicit directions for dietetics, forbidding some meats and recommending others, always strongly urging cleanliness. Circumcision is especially ordained, and, undoubtedly, the ancient Hebrew empirics practised lithotomy and were as successful as the average cutter for the stone. The great advances made by the Hebrew physicians were in the Middle Ages, and in the Talmud there are many directions that a modern surgeon would do well to follow.

In the Odyssey, Homer praises the physician ex-

*Herbert Abraham: "Improved Instruments for the Physical Testing of Bituminous Materials," Proceedings of the American Society for Testing Materials, Philadelphia, Pa., vol. xi, 1911, pp. 678-9.

ccedingly. "A physician outweighs many other men (in value)."

ἰατρὸς γὰρ ἀνὴρ πολλῶν ἀντάξιος ἄλλων

The Homeric physician, like the Homeric magistrate, daily made his rounds and prescribed on the market place for the patients who came to see him. Wealthier patients were treated in their own homes or in the homes of the physicians (ἰατρικὰ ἐργαστήρια). These houses were well fitted up for instruction and contained all the necessary appliances wherewith to perform operations. The rooms were well lighted and the students were allowed to try their hands on minor operations, especially on the poor, non-paying patients.

Hippocrates, the ancient apostle and teacher of ethical and scientific practice, gives many concise directions in his Corpus Hippocraticum and makes special mention of lithotomy. In his famous oath which every physician swore to with reverence and fear, appears this clause: "I swear by the gods to cut no one for the stone, but to leave this operation to those whose profession it is." This clause was inserted not that the physician was unable to perform the operation, but that it was beneath his dignity to soil his fingers with immodest manipulations. Quacks and empirics were indeed grateful for this delicacy on the part of the doctors.

The Pythagorean school, which preceded Hippocrates, neglected most of the surgical operations and employed for their remedies cure-alls composed of fanciful combinations, whose ingredients were frequently odious to the taste and imagination. These physicians recommended salves and poultices, and especially were they skilled in theurgical usages. Their expiations and spells and magical incantations were a lore in themselves. They believed in theory. "Theory is the flower, not the root of experience."

One of the aphorisms of Hippocrates would suggest the helpless condition in which the physician found himself in the face of illness: "Do good, or at least do no harm!" They considered it a sign of lack of surgical dexterity if one should fail to pass a catheter into the bladder, and if the presence of a stone in the bladder was not recognized. Nephrolithiasis and vesical calculi were observed to be common diseases. Many theories were advanced by the followers of Hippocrates as to the etiological factor in this disease. A theory that is worthy of note is the supposition that prevailed, that lithiasis was due to some impurities in the drinking water, as lime or sand, and that these were collected in the kidney and bladder and there formed stony concretions.

Though surgery was practised by most physicians, the operations of lithotomy and castration during the age of Hippocrates were relegated to the untutored empiric. The latter performed these operations while the physician and the priest stood by, the one recommending suitable ointments for the wound, while the other prayed to the gods to send a speedy cure. Abscesses in the neighborhood of the kidney, also possibly due to stone, were treated by nephrotomy as soon as edematous swelling became visible.

After Hippocrates, the great progress made in medicine was in Alexandria. There, under the learning-loving Ptolemies, the doctors found good patronage and could, therefore, pursue their studies of herbs and anatomy. Herophilus of Chalcedon, pupil of Praxagoras and Chrysippos (300 B. C.) was famous for his great knowledge of medicine and for his surgical skill. It was he who discovered the torcular Herophili in the cranium. He was a brilliant anatomist and he made much progress in anatomical terminology. He treated retention of urine by a particular kind of a catheter which long afterward bore his name. Eudemos and Manteas were two other great surgeons of that era. But the Alexandrian school made more progress in theorizing than they did in practice, and this disgruntled the practically inclined, who, as Celsus says, were more interested in the treatment than in diagnosis and prognosis. A few of their tenets are very illuminative of their beliefs:

"The husbandman and the navigator are not trained by disputations but by practice."

"Diseases are not cured by talk, but by drugs."

"The important question is not what causes disease, but what dispels it."

Heraclides of Taras was a pupil of Manteas, but he sided more with the men who were striving to obtain practical rather than theoretical knowledge. Learned as he was in pharmacology, he was also noted for his surgical abilities. He made great progress in the treatment of fractures and dislocations, and he was especially famous for his herniotomy operations. He did not consider it below his dignity to cut for the stone, and indeed he improved the operation of lithotomy.

As a lithotomist, Ammonios had no equal among the ancients, and patients flocked to him from foreign lands. He not only was proficient in doing the perineal section, but he invented an instrument whereby stones that could not be extracted through a small incision might be crushed and washed out. He is perhaps the first famous surgeon who had recourse to lithotrity, or crushing of the stone, and for his great skill and dexterity he was called λιθότομος.

It seems that lithotomy was destined to play its share in a political intrigue of that time. The story extant does not at all reflect credit upon the surgeons of that epoch. In order to get rid of Antiochus, the ten-year-old son of Alexander, King of Syria, Diodotus, his guardian, hired certain surgeons to kill him. Under the pretence that the child was suffering from stone in the bladder, they performed lithotomy on him, and so managed it that he did not survive the operation.

With the decline of Greece and the development of the Roman power there was a continuous migration of Hellenic physicians to the city on the Tiber. The boorish Romans, untutored in the fine arts, could not appreciate the cultured Greeks. Cato, the great philosopher, would not permit a Greek physician in his household and indeed he wrote several epistles against allowing the Greeks to practise in Rome. It is true that on many occasions the foreign physician, driven to it by poverty, aided certain wealthy patricians in their debauches and in their plots for poisoning their enemies. It is instructive to note the fate that befel Archagathos, a Greek immigrant in Rome. At first he was greatly honored and his skill and dexterity were so much praised that the Senate of Rome conferred on him the thanks of the city. But once in his large and lucrative practice he lost a patient, who died following an operation. The fickle mob forgot his great abilities, and in their rancor drove him from the city, confiscating his property (219 B. C.).

The greatest empiricist was Themison. His pupil, Thessalos of Tralles, son of a weaver, and

contemporary of Nero, was the greatest quack of his day. He very much restricted surgical interference in case of disease. He believed in practising on the minds of his patients and, indeed, his prescriptions contained many harrowing ingredients. He was the greatest exponent of what is now known as the Methodist School of Medicine. Another follower of Themison was Meges of Sidon (20 B. C.), who invented several new instruments for facilitating the lithotomy operation.

A. Cornelius Celsus (25 A. D.) was one of the greatest encyclopedists of ancient Rome. He so logically and clearly reviewed the history of medicine up to his time, that we owe to him much of the knowledge that we possess of ancient medicine. In his book "De Medicina Libri Octo," we have a complete résumé of the history of medicine previous to him and during his time. It is written in elegant Latin and its diction rivals Tacitus' history. Books 5 to 8 are devoted entirely to the art of the surgeon. In book 4, chapter 10, we find this oft quoted statement: "Notae vero inflammationes sunt quattuor, rubor et tumor, cum calore et dolore." He gives an excellent account of the lithotomy operation, describing fully the indications and contraindications for that procedure. He also describes an operation for subcutaneous urethrotomy on patients who have their urethra blocked by a calculus.

The Pneumatist School, founded in the first century A. D. by Athenaios of Atteleia, contended that all phenomena were dependent on the vital air. They studiously investigated the causation of disease and divided the etiological factors into extrinsic causes, intrinsic causes and the causes due to evil spirits. Stone in the bladder, they considered as evidence of some internal disturbance of the body (αἴτια συνέκτικα) instead of its being due to some extrinsic substance ingested in drinking water.

Archigenes and Heliodorus were two famous surgeons of that time. The latter has made notable contributions to the knowledge of hypospadias and stricture. Leonidas of Alexandria improved many operations and was especially noted for his skill in cutting for hemorrhoids. A special volume on bladder stone disease was written by Aretaios of Cappadocia in the latter half of the first century after Christ. He described in detail the technique of the operation, and gave good advice as to symptoms and prognosis.

In the second century A. D., Rhuphos of Ephesus wrote a learned work on urogenital disease. In the treatment of inflammation of the urinary bladder, he forbade the use of the catheter, and he especially enjoined care in avoiding irritation of the diseased mucosa. He also described vesical hemorrhage and cystic paralysis. In his diagnosis of vesical calculus, he gave explicit directions for a bimanual examination for the recognition of the presence of a stone in the bladder. He prescribed for all the urinary affections, and detailed the lithotomy operation.

Galen, the greatest successor to Hippocrates in ancient times, makes the statement which is quite current even now, that renal calculi are of the same origin as the gouty deposits in the joints of patients suffering from podagra. In one of his books he states that vesical calculi occur chiefly in boys. In the treatment of stone disease he prescribed cures identical with those for gout. Ass's milk, and wine mixed with honey were thought to be especially efficacious. Of drugs, he used diuretics like myrrh, parsley, caraway, ammoniacum, and the powder found in sponges. In the chapter on treatment he described catheters and a calculus forceps whereby stones could be extracted through the incision, or else crushed before delivery.

Perhaps the greatest surgeon of antiquity was Antyllos. He stated careful directions for performing lithotomy. He gave details concerning the indications and contraindications for that operation.

In Rome specialization was carried to the highest point. A doctor would not for a moment entertain the idea of performing any manual labor on his patient. Galen, speaking of Roman practice, says: "Since I lived in Rome I had to make many concessions to the customs of the capital and leave most of these things (surgical procedures) to the so-called surgeons, eye doctors, aurists, hernia specialists (lithotomists), etc."

Quintus Seremus Samonicus (211 A. D.) recommended goat's urine to be drunk in vesical calculus. He also reviewed the treatment, both palliative and operative, of all urinary diseases. Perhaps the first man to write an extensive monograph on renal stones was Philagrios of Epirus, who practised in the first century A. D., in Thessalonica. Only a few isolated fragments of his work remain, but these are enough to show that he was learned in his craft. He discussed minutely the causation, diagnosis, and treatment of renal and cystic lithiasis.

Caelius Aurelianus was a medical encyclopedist who lived in the fifth century. His masterpiece is a compendium of the whole knowledge of medicine entitled, "De Morbis Acutis et Chronicis." In the chapter devoted to the discussion of the diseases of the genitourinary system, he dilated upon the symptoms and diagnosis of bladder stone. Among the diagnostic signs he described the characteristic attack of renal colic. He stated that the pain radiates to the pubes, navel, perineum and scrotum. The diagnosis was to be effected not only by subjective symptoms, but also by a sound, which was to be introduced into the bladder and with which the stone was to be felt.

In the Talmud we find many references to hygienic laws, and also directions for performing surgical operations. Many operations are roughly described, but circumcision is especially detailed. The surgeon was to wear a leather apron and was to keep himself very cleanly. They knew that the less a wound was manipulated, the surer was the cure. One of their recommendations was not to touch open injuries, for "the hand causes inflammation." Among the surgical instruments mentioned are large and small knife, trephine, lancet, and a device known as the *Nail* for blood letting. The treatment of vesical stone is quite curious, and among the various procedures we notice the following: "Catch a louse from a man and another from a woman; fix the one upon the breast of the woman and the other upon the male organ of the man; then let them urinate upon a blackberry bush while somebody watches whether the stone escapes."

In the sixth century there lived Aetios, who wrote the famous work called "Tetrabiblon." He spoke in an erudite manner on the history of surgery. He mentioned Philargios as the originator of the method for the removal of impacted stones by urethrotomy. In chapter 24, he described a case of vesical mole (the first case reported). The perineal route for the removal of cystic calculi was carefully described, and many important admonitions

were given to the practitioner. He suggested that the knife used for the lithotomy operation should be protected by a tube. He also described cutting for the stone in women.

Alexander of Tralles (525 A. D.) wrote an excellent treatise on the differential diagnosis of renal calculi. He especially laid stress on the differentiating signs from intestinal colic. Pain in renal colic (he asserted) is more severe and more circumscribed and is chiefly felt in the loins. Examination of the urine reveals a gravel-like sandy deposit. Another point in the differentiation is the fact that cathartics will relieve an attack of intestinal colic, but will have no effect on the crisis of kidney stone.

Paulos of Aegina, who lived in the seventh century A. D., wrote voluminously on medicine. He was the first to advance the theory that gout is a disease of metabolism. According to his view, "as a result of insufficient assimilative powers of the various parts of the body, there is formed from the superfluous food, together with indolent habits of life, a morbid humor, which is first attracted by a weakened joint, but may also lodge itself in the liver, spleen, kidneys, etc." In the chapter on urinary diseases, he gives interesting descriptions of catheterization and lithotomy.

With the decay of Byzantine civilization, there was a general cessation in the progress of all science. The superficial gloss that replaced true culture evinced itself in the shallow writings of that time. The intolerance of the church and the idea that whatever was old was excellent, and that nothing modern could be of value, stagnated human endeavor. Instead of expressing their own ideas, they modified and rewrote the thoughts of the ancients. There was a dearth of talent, and the ingenuity of those who were exceptionally brilliant was wasted on purposeless tasks.

Theophilos, with the characteristic empty verbosity of the schoolmen, wrote a treatise on the examination of the pulse and on uroscopy. Another author, Jeannes Actuarius, who lived in the thirteenth and fourteenth centuries, also wrote voluminously on the examination of the urine and on sphygmology. In his monograph "On the Urine," many kinds of sediments are named according to their colors and consistencies, and graduated glasses for the measurement of the depth of these deposits are recommended.

During the Middle Ages, the Arabs functionated as the archives wherein the knowledge of the ancient Greeks and Romans was preserved. They retained in original and in translation the philosophy of Plato, the learning of Aristotle, and the knowledge of Hippocrates. The greatest physicians and surgeons of the medieval period were Arabs and Jews. The Christian potentates had Hebrew court physicians and, though they persecuted his brethren, they were careful in protecting their doctor.

The Arabian Hippocrates is Rhazes, who lived in the ninth century. He was a conservative who believed more in the usage of simples than in the radical treatment of disease. "When thou canst cure by diet use no drugs, and where simple measures suffice, use no complex ones." was one of his aphorisms. His work is entitled "*Al Hawi*," or the Contents of Medicine. Rhazes considered retention of the urine to be due either to stone or to cystic paralysis. He taught that if medicines are unavailing in this disease, recourse must be had to the catheter.

Avicenna, another great Arabian physician (980 A. D.), described lithotomy fully. Abul Kassim and Avenzoar were noted surgeons of that epoch. The latter considered it below his station to perform surgical operations. In his young student days Avenzoar had acquired very valuable practical experience, and though he did not undertake any operative procedures when he was already famous, still his acquaintance with surgical technique caused him to be much sought after by all classes of patients. Lithotomy alone he would have nothing to do with, because of the indecency and the immodesty. Abul Kassim thus gives the directions for the removal of a bladder stone in a woman: "The finger should be introduced into the rectum of virgins, into the vagina of married women; then an incision should be made, in virgins to the left and below into the labium, in married women between the urethra and os pubes, so that in both cases the wound is oblique."

Moses ben Maimon, known as Rambam, the greatest Jewish physician and philosopher, might well be considered here, since he practised among the Arabs. His book of Aphorisms was studied in all the universities. Though he usually agreed with Galen, he pointed out wherein the Pergamite erred. He commented upon the operation for circumcision, but he did not consider lithotomy of enough dignity to be written about.

Due to the fact that the Arabian doctors would not treat gynecological diseases if they had to expose the genitalia of their patients, there developed a caste of women surgeons, whose function it was to aid the female patients in those diseases to which the physician refused to attend. These female practitioners attended the women in their confinements and gave them the necessary clysters and injections when the case required them. Some of them became very proficient and were able to perform lithotomies and embryotomies.

Among the Teutonic nations there developed a variety of surgery similar to that of the ancient Hindoos. Skulls have been found of very ancient Vikings who have had their cranium trephined and have survived the operation. Payne in his book on Anglo-Saxon Medicine details many operations then current for setting of fractures, reducing of dislocations, treatment of open injuries, and methods of amputation of gangrenous extremities. The Druid priests and priestesses performed lithotomy, using very rough instruments and drugging the patient before the operation. In the last century it was yet common among the members of a certain tribe of Australian aborigines called "Kalkadoona," to cut the urethra with a flint knife, and in case this instrument was not handy, to use a sharp mussel shell.

In the fourteenth century there were current in England peculiar prescriptions for all diseases, and we find the following advised as an excellent lithotryptic:

"For to breke the stone that ys in a man—Take a quike hare in marche and sle hym and tak all the bloud and put the hare in the bloud, guttys, scyn, heyde, and feyte, and a lytel milk and put al these into a pot so that the pot be ful, and take elysaudre route and the sed of Saxfragie and the route of filipendula and the route of tyrmentylle and the curnellys (kernels) of chyrrystones and gromel sed and the pise (?) that is in a maive, and of dawe bred, take al these and put hym in water or in ale at nygt and gyf hyt the man that haf the stone and

he shall keuery (recover)." Those patients suffering from gravel disease were advised to drink the following:

"Who-so hath the stone—Take gromeyle sed and parsile and the ryde netyle (Red Nettle) and violet and rechelus and cyrnellys of chirestones and stamp hym and tempre hym wyth ale and drink hyt."

There were current in those days many vulgar ideas and remedies about the stone disease. In 1575, Gascoigne, in his "New Art of Venery," remarked that *"his pyssel serves to scour the gravel of the stone."* Another author hinted that *"Ale made with hoppes is unwholesome for the stone."* From Lean's Collectanea, I have gleaned several French admonitions regarding nephrolithiasis:

"Contre ceux qui conseillent et ordonnent l'acte vénérien contre la gravelle, pierre et autres maux de reins." And again,

"S'il y a raison de dire qu'il ne faut verser de l'eau en la chambre de celui qu'on a taillé pour la pierre."

"D chausser toujours première la jambe que respond au costé de la douleur pour guérir de la nephritique."

Gilbert of England, called "Laurea Anglicana," was famous for his prescriptions. He used to treat bladder stone by giving the patient to drink the blood of a he-goat which had eaten diuretic plants.

In the Middle Ages, with the advent of the power of the church, learning was fostered only in the monasteries and abbeys, and the monks, besides shriving the soul, took upon themselves the duties of doctors. Certain monasteries in Italy became famous for the medical and surgical skill of the monks. In the Abbey of Monte Cassino, near Naples, many remarkable cures were performed. It is related that Saint Benedict himself, removed a bladder stone from King Henry II of Bavaria (983 A. D.) while the monarch was asleep; and not only that, but he cured the wound during the night. Another instance of the perpetration of a remarkable pious fraud!

Until some time in the middle of the fourteenth century, the priests cared for the bodies of their flock as well as for the spirit. But they made no progress in the surgical arts, and only followed the ancient directions of the pagan doctors. In certain cities there developed trained guilds of lay surgeons, and in some towns in Germany, these were hired by the community to treat the indigent. In various cities herniotomists were appointed to operate on all patients suffering from rupture. Later on the German towns even regulated the fee that a lithotomist was to receive. Thus in certain communities he was granted a license with the strict enjoinder that for each lithotomy operation he receive fifty-one marks, if the patient recover, and half that sum if he die.

The doctors, that is the college graduates who spoke only Greek and Latin of Hippocrates and Galen, were not supposed to touch their hands to the knife. In the city of Uberlingen, there is on the records a tragic-comic episode that befel a certain Doctor Val. Butzlin. The latter had engaged Master Conrad Angelberger, a professional herniotomist, to operate on the scrotal hernia of his son. The surgeon seems to have utterly failed in the operation and the burghers smiled at the plight of Dr. Butzlin. The case is thus reported in the quaint German of that time: "Doch hat er, wiewol er siner kunst ein bewerter und erfarner maister sonst gewesen, dazumal so grob gefelt, dasz er dem guten jungen den gesunden stain geschnitten, den schadenhaften hat er ime gelasen. Also ist er umb das klainet vergebenlich und one alle not kommen."

John Arden is perhaps the first surgeon worthy of that name in England. He lived in the fourteenth century and was a native of the town of Newark. Inventor of many admirable instruments, he greatly improved the surgical technique of his time. He was famous for his success in the treatment of fistula-in-ano, and for his cutting for the stone. He was the author of several treatises which are preserved intact in the British Museum.

The most famous schools of medicine during the dark ages were in Italy. The University of Salerno was celebrated for the very great men that graduated her classes. Ruggiero of Palermo (1210 A.D.) was the most noted of the Italian surgeons. He was the first to describe hernia pulmonalis. He was respected for the skill with which he performed the most dangerous operations. He frequently practised stitching the intestines and he was the first medical writer to use the term "seton." Among the operations he described were resection of the lower jaw and central lithotomy. His works are incorporated with the writings of Roland of Parma, a student of his. In the fourth book of their work entitled "Glossulæ Quattuor Magistrorum Super Chirurgiam Rogerii et Rolandi," there is a complete description of symptoms and treatment of vesical calculus.

Another famous Italian anatomist and surgeon was Mondino dei Luzzi, also known as Raimondino, who was born *circa* 1276. In his lectures he stated that renal stones, if small, pass through the ureter; if large, they are incurable except by operation, and *that* is to be avoided. The operation for performing lithotomy was thus described: "The patient being in the proper position, the stone is conducted to the neck of the bladder by the finger in the rectum; and incision is made, and the stone is pulled out with an instrument, called the *trajectorium*."

Among the Italian physicians was the far famed woman doctor, author of "De Mulierum Passionibus," who lived in the middle of the eleventh century. Dramberg and Henderson doubt very much whether this individual, who bore the name Trotula or Eros Julia was a woman. In her book "Erotis Medici, Liberti Juliæ, quem Aliqui Trotulam Inepte Nominant, Muliebrum Liber," mention is made of herniotomy and lithotomy.

In the fourteenth and fifteenth centuries there was no marked progress in surgery in general, or in lithotomy in particular. When a certain new discovery was made in surgical technique, it was kept secret that only the descendants of the inventor might profit by it. This would put one in mind of the Chamberlen family who had in their possession the secret of the delivery forceps, and only made it public when Roger van Roonhuysen of Amsterdam bought it of them for a certain sum of money. A similar case occurred in the sixteenth century. Lawrence Colot, a contemporary of Ambroise Paré, improved the lithotomy operation. He used the staff and the other instruments of the "apparatus major," but he kept these improvements secret and his descendants derived much profit from this monopoly.

In the sixteenth century a radical step was made in the treatment of vesical stone. Pierre Franco was a noted French surgeon. He was born in Eurriers near Sisterom in Provence. He practised in

Freibourg, Berne and Lausanne, and enjoyed a national reputation. In 1556 he published his description of the suprapubic method for the removal of cystic concretions, in a treatise entitled, "Traite contenant une des parties principales de la chirurgie, laquelle les chirurgiens herniares exercent." An Italian surgeon of the same century, Antonio Benivieni (1502) of Florence, was noted for his peculiar method of removing vesical calculi in women by dilatation of the urethra.

In England, James Douglas (1675-1742), an excellent anatomist and one of the most brilliant surgeons of his time, was the first to demonstrate the high operation for stone. He published "The History of Lateral Incision for Lithotomy." Another surgeon, William Cheselden (1688-1752), also an Englishman, was a famous lithotomist and ophthalmologist. He reported unfavorable results with the Franco operation and he, therefore, modified a lateral lithotomy operation of a contemporary of his, Raw. His reputation was very great and his skill was so admired that there are many legends connected with his name. He is reputed to have performed the operation of cutting for the stone in fifty-four seconds. His mortality figure was very low. He lost six out of eighty patients upon whom he had performed the perineal section. John Yelloly remarks of him: "Cheselden is generally considered as having lost only one patient in ten and a half in his hospital lithotomy practice, but the summary referred to, of twenty deaths in 213 cases, applied only to the success of his improved lateral operation. His great success was with children."

Frère Jacques was a Franciscan monk. In his youth he worked as a day laborer; he never had any schooling. Though he had no knowledge of anatomy nor for that matter any cognizance of any medical science, he was one of the most famous lithotomists of his time. He invented the lateral method of cutting for the stone, and he is said to have done five thousand lithotomies. Le Cat (1700-1768) was another Parisian of that time who was a noted lithotomist. He is also famous as an opponent of the doctrines of Haller.

In 1753 Hawkins invented a cutting gorget for lithotomy. Benjamin Bell in a "System of Surgery" (1783) described in detail all operations in vogue at that time for the treatment of renal and cystic calculi, recommending especially the lateral lithotomy section of Frère Jacques and reporting very sinister results with the suprapubic incision of Franco. Towards the latter part of the eighteenth century, an episode occurred which is quite worthy of mentioning. A certain Mrs. Stevens of London was reputed to cure bladder stones with the aid of various remedies. Only the wealthy could afford to pay the extravagant fee that she demanded, and there arose, therefore, a clamor from the poor classes demanding that Parliament buy the secret from the woman. Accordingly the House of Commons passed a bill that the secret be purchased for the sum of five thousand pounds. Their surprise was great, however, when they learned that the terrible remedy was simply milk of time!

About this time there was a tendency to crush the stone rather than submit the patient to a cutting operation. Ammonios of yore was the first to do lithotrity, but he did it only to facilitate delivery of the calculus through a small incision in the perineum. Frère Jacques suggested that crushing be always resorted to, but this advice did not gain much ground. In 1819, Gunthuisen of Munich, and in 1824, Civiale of Paris, wrote fully on the method of lithotrity and reported very brilliant results with this procedure. Jean Civiale was born in 1722 in Threzac. His works on bladder diseases are entitled: "Nouvelles considerations sur le retention d'urine" (Paris, 1823), and "De la lithotritie" (1826).

In the nineteenth century, with the advent of asepsis and antisepsis, the lithotomy operation has been gradually improved. The greatest progress made in this respect was by American surgeons. Alexander Eddy Hosack of New York, who was the first practitioner in this city to administer ether anesthesia, wrote a paper entitled, "Twenty-three Cases of Lithotomy by a Peculiar Operation, All Successful." In it he states that following a German idea, he operated without dividing the prostate gland, and in all cases were his efforts rewarded with complete success, so that not only did he have no mortality but all his patients retained their powers of procreation (an unhoped-for result in his day).

In 1876, Dr. Henry Bigelow of Boston, one of the most famous American surgeons of his time, described a method whereby the mortality rate was reduced to three per cent. This procedure he termed lithopraxy or rapid lithotrity.

Nephrolithotomy was first performed in 1882 by Henry Morris for the removal of a stone from a healthy kidney.

Amongst other noted American lithotomists, several should be mentioned. William Baynham (1749-1814), a native of Carolina, was a famous operator for vesical stones. He gained William Hunter's praise for his method of injecting anatomical specimens. Benjamin W. Dudley (1785-1870) was a pupil of Sir Astley Cooper. He it was who founded the medical school of the University of Transylvania in Lexington, Kentucky. He was fond of using the blunt gorget in his lithotomy operations. Though he used the lateral method, he had no death in a series of one hundred lithotomies. Dr. Eve of Nashville, Tennessee, was also a noted cutter for the stone.

There are several famous men in literature and in medicine, who have suffered from renal or bladder stone. In England, the land which is noted for its hearty drinking, gout and gravel have claimed many a victim. The redoubtable Sir John Falstaff was very much in doubt whether the pain in his great toe was due to syphilis or gout. He self-consolingly remarks: "A pox of this gout! or a gout of this pox! for the one or the other plays the rogue with my great toe. It is no matter if I do halt. I have the war for my colours, and my pension shall seem more reasonable. A good wit will make use of anything, I shall turn diseases to commodity."

It is not surprising, therefore, that the corpulent knight should send his water to be examined by a doctor:

Falstaff: Sirrah, you giant, what says the doctor to my water?

Page: He said, sir, the water itself was a good healthy water but for the party that owned it, he might have more diseases than he knew for.

[Henry IV—part 2—i—2.]

In another part of Shakespeare we find special mention of "loads o' gravel i' the back" and "bladders full of imposthumes" as complications of syphilis.

English physicians were many times themselves

sufferers of podagra and stone. Sydenham was afflicted with both of these diseases, and he thus described his method of treatment:

"In the morning, when I rise, I drink a dish or two of tea, and then ride in my coach till noon; when I return home, I moderately refresh myself with any sort of meat, of easy digestion, that I like (for moderation is necessary above all things), I drink somewhat more than a quarter of a pint of canary wine, immediately after dinner, every day, to promote digestion of the food in my stomach, and to drive the gout from my bowels. When I have dined, I betake myself to my coach again and when business will permit, I ride into the country, two or three miles for good air. A draught of small beer is to me instead of a supper, and I take another draught when I am in bed, and about to compose myself to sleep."

He suffered from gout from the age of twenty-five, and at the age of thirty-six he began to have gravel. His agonies were extreme and he longed for death. Speaking of a patient who is afflicted with these illnesses, he says: "He suffers until at last he is worn out by the joint attack of age and of disease, and the miserable wretch is so happy as to die."

Another physician, the great Italian pathologist and anatomist, Jean Baptiste Morgagni, was a sufferer of nephrolithiasis. His remedy was to take half a drachm of the carbonate of potash night and morning, gradually increasing the dose till he took three drachms during the day "The acid of the urine became saturated, the pains in his loins diminished, his urine became less loaded and potash was at length found in that fluid in excess."

Michel Eyquem de Montaigne, the greatest French essayist, was a firm disbeliever in all things medical. Emerson has called him "Montaigne the Skeptic," and we needs must believe that he was very skeptical when it came to dealings with doctors. He suffered from painful colics all his life, and, in order to cure himself, he traveled to all the famous mineral springs in order to drink of their healing waters. He seldom consulted a physician, and if he did, it was only to listen to his advice and follow out those instructions which *he* considered logical. "My aversion to medicine," wrote Montaigne, "is hereditary, like my disease. My ancestors detested medicine by some occult and natural inclination." When his best friend died, he blamed the physicians for his calamity. "The doctors," he says, "do not know anything about the police of this little world. Because they would not stop a dysentery for fear of bringing on fever, they killed me a friend who was worth more than them all put together." He especially feared the lithotomy operation, and he forbade anybody to operate upon him even in the direst necessity.

Among other victims of "this sharp and craggy stone that cruelly pricks and tears," we may mention Bacon, Boerhaave, Newton, Harvey, Fothergill, and Scarpa. Benjamin Franklin, though he suffered much from podagra as his interesting dialogues with "Madame Gout" would testify, did not seem to have been a victim of gravel. Soldiers, though they were fearless on the battlefield, rolled with agony when that leveler of all human ranks, pain, gripped their very vitals. Napoleon Bonaparte, Peter the Great, Louis XIV, George IV, Cromwell, and doubtlessly other warriors and rulers yielded ingloriously to this fell disease. Even the statesman, Horace Walpole, found his fluent tongue and brilliant oratory unavailing during the periodic attacks of the passing of the stone.

SOME BLUNDERS MADE BY NATURE IN TREATING DISEASE.

By AUGUSTUS MAVERICK, M.D.,

SAN ANTONIO, TEXAS.

It was Voltaire who made the remark that "the physician amuses the patient while nature cures the disease." Unfortunately there has always been much that is true in this aphorism, but if the author of the "Age of Louis XIV" could return to-day with a gangrenous appendix or a plaque muquese he would have to confess that the physician is becoming as useful as he is amusing. As a matter of fact, the physician has always owed his livelihood to nature's inability to care for the sick. If nature was famed for its skill at relieving pain, draining abscesses and killing invading parasites, the physician would starve to death; but judging by the stream of newborn healers which pours from our colleges as fast as the printers can turn out the diplomas, nature leaves a large field for improvement. There is still a lot of talk of adhering strictly to natural methods in the treatment of disease, but those who talk the loudest must confess that in severe diseases where we "leave nature to take its course" the outlook for the patient is always the worst. To turn a very ill person over to nature is like sending a dying consumptive to Egypt. Compare the breathless victim of pneumonia or the stuporous typhoid patient, untouched by cold water, awaiting the verdict of the unknown, to the surgical case of gallstones or the prey of the anapholes well dosed with quinine. Is nature's treatment for pain, by causing the sufferer to faint from exhaustion, better than the physician's hypo of morphia, or is nature's effort to squeeze a kidney stone through sixteen inches of tubing, one-fourth its diameter, more preferable than ether,

antisepsis and the knife? It is common to hear a drug or system of treatment recommended because "it is nature's own remedy." Would it not be better to say that it is *our* own remedy and twice as good as anything nature has to offer? Would this be blasphemous to a system of government which puts us on earth to fight unceasingly for our life? It is the surgeon who to-day is leaving the least to nature and doing the most for his patient; it is the internist who lags behind in his treatment under the delusion that what is natural is best and is making nature his guide rather than the experimental laboratory worker.

Inflammation and Scar Tissue.—Not long ago an Eastern surgeon in suturing a wound of the intestines left the lumen too small and chronic intestinal obstruction resulted. The surgeon suffered severely in the hands of local gossips, for the most inexperienced holder of a medical diploma was expected to know how to sew a gut and still leave it open. Yet, this trick is performed every day by nature in healing dystenteric and syphilitic ulcers of the bowel; the wound is bound with scar tissue which shrinks with age and finally strangles the gut it came to heal. Scar tissue is nature's cureall for wounds. When a cut is made through the skin the edges are brought together by a delicate network of scar tissue threads and so neatly is the work done that in time only a seam is left to mark the once unsightly deformity. This scar at first is pink from a rich supply of capillary vessels, but as scar tissue grows older it is its nature to contract and squeeze shut the vessels which give it life; so that in time a white, tough, puckered scar remains. All this is of no great consequence on the skin, except for a possible distorted face or crippled hand, but it plays havoc within the body where the structures are more delicate. Take the heart valve which is left ulcerated by an attack of endocarditis; the inevitable scar tissue starts its patchwork and makes a neat job of covering over the denuded areas, but instead of leaving well enough alone it goes on contracting and in time a useless, puckered bunch of valve leaflets remains, the heart works in vain to overcome the backflow of blood and the days of the victim are numbered. Among numerous other examples of serious results from scar tissue may be mentioned strictures of the pyloris, rectum, and urethra; deformed joints; cirrhosis of the liver; Jacksonian epilepsy; chronic Bright's disease, and arteriosclerosis. Even with a strictured pylorus the victim manages to find some enjoyment in life, but this is not all that is sometimes in store for him; only too often the scar tissue sets up such an irritation of its own that cancer takes root as the result. That this is frequently the final stage in nature's long drawn-out effort to heal an ulcer of the stomach, a torn cervix uteri, or a scarred gall-bladder is unfortunately common knowledge. No quack ever handed his patient a worse deal than this. In old age the organs have become so riddled with this weedy substance, scar tissue, that life is squeezed from the body many years before the proper time. Suppose we had a scar tissue which, after it had performed its duty, stayed pink and soft and never shrank—what an ideal remedy this would be!

Acute inflammation is also a fair example of the crude way disease is often handled by nature. All the swelling, pain, and discomfort of an infected area is not due to the invading germ but to the natural remedy. Of course we should be grateful for any protection at all from foreign irritants, but we must confess that this process is frequently rather far fetched. Does not the swelling about the glottis, which cuts off the air from the little chap, the victim of croup, seem a rather drastic treatment for a slight irritation of the larynx, and is not this also true for the infant who cannot suckle because nature is treating a slight cold in the head, and again, the patient who is dyed a deep yellow because the bile ducts are swollen shut from a catarrh which otherwise would pass unnoticed? When inflammation goes on to suppuration and an abscess forms it is certainly time for us to interfere; left to itself the abscess may, after a long and torturing interval, dry up and leave adhesions tugging on neighboring structures, or it may, with agonizing pain to the patient, point and drive its deadly contents straight into the peritoneum or some other vital field. Who is there to-day with an abscess of the appendix who will place himself in nature's hands when a surgeon is nearby?

The tendency of different mineral salts from the body juices to collect about irritating foci is often applauded, and well so, for it is in this way that a tuberculous area is imprisoned. However, there are times when this process does more harm than good. Take a mass of typhoid bacilli which is proving a nuisance within the gall-bladder; nature turns loose an abundance of bile salts which deposit about groups of bacilli to form thick shells. Are the bacilli walled off and made harmless by this method? Yes, but there are left ten to a hundred or more gallstones which play the very devil with the unlucky owner.

Overdosing.—We have learned by experience that moderation in treating disease is as important as moderation in everything else, and that the most harmless remedies become poisons in overdoses. Nature often gives overdoses and thereby does more harm than good. Fever is a good example. Fever is now recognized as nature's attempt to make the blood too hot for the comfort of invading microbes. A moderate amount of fever evidently aids the patient, but when it becomes excessive the question arises: which is causing the most damage, the bacterial toxins or the heat? The headache, anorexia, malaise, rapid heart, hurried breathing, scanty kidney elimination, nervousness, delirium, stupor, cloudy swelling and the whole train of symptoms of the acute infections—how many are caused by the disease, the toxins, and how many by the natural remedy, the fever? The benefit derived from the use of plain cold water in typhoid fever will help to answer this question. Another example of a natural remedy carried to excess is the hypertrophied heart. When imperfect closure of the valves demands more work of the heart its muscular walls thicken to supply the extra power. If this method made up for the deficiency and kept step with an ever-increasing deficiency, well and good, but it does not. The heart goes on enlarging and pounding away far beyond the demand made upon it and the patient relieved of some little tendency to dropsy or shortness of breath now suffers more distressing symptoms. If this ability to increase in size were unlimited the natural treatment of heart disease might remain merely troublesome and not prove dangerous, but there comes a time when the growing muscle cannot receive enough blood to nourish it: it is the old cry of no food, no work, and the heart, unable to keep up the pace it has set, fails and fails rapid-

ly. Here is an example of how a little prudence on the part of nature could keep the heart active many years after it has ceased to beat, for it is not nature, but the physician who, with his drops of aconite, prolongs the patient's life, or, at a later date, with his digitalis, keeps beating the heart long since thrown aside by its maker. A high blood-pressure is commonly a bad natural therapeutic measure. In attempting to compensate for what the failing heart and kidneys refuse to do, the pressure in the vessels rises often above 200 mm. of mercury. Any minute such a man may drop unconscious from apoplexy unless the physician with his nitrites can undo some of the mischief by bringing the pressure down. A cough, as we know, is nature's method of blowing irritating matter from the bronchi. We can all recall instances of how this is frequently carried too far. There is, for example, no sense in making a child cough until it vomits or breaks a subconjunctival blood-vessel, for all the good it does in whooping cough. The congestion of the mucous membrane of the larynx and its injury by being brought into violent contact following a severe paroxysm of coughing, surely does more harm than good. The cough of phthisis is certainly an unwise prescription when it keeps the patient sleepless and nervous or encourages hemorrhage or the dissemination of infection. Diarrhea, which persists after the bowel is as clean as a gun barrel, the profuse nasal flow from a simple cold, the edema which closes the glottis, the bony callus which entangles the nerve—these are but few of the many other examples of how nature overdoses its patients.

Antibacterial Properties of the Blood.—Much is heard to-day of the wonderful natural properties of the blood to kill invading bacteria and neutralize their toxins and of our ability to aid nature in the use of these. When we add antitoxins or bactericidal products to the blood, we are merely imitating nature, not doing something better. Of course in adding, for example, diphtheria antitoxin to the blood in large quantities and thereby saving an urgent case of diphtheria, we are doing something which in the time allowed nature could never have accomplished, but, nevertheless, the method employed is purely nature's. Armed with antitoxins, antibacterial sera, and preventive vaccines, our task of fighting infectious diseases will be lightened for some time to come. It is not these, however, but chemical compounds like salvarsan, selenium with eosine and mercuric succinimide, purely the work of man, which will constitute the ultimate goal of therapeutics. Suppose the blood had naturally a *therapia sterilisans magna*, instead of all these million and one different antitoxins, opsonins, agglutinins, precipitins, bacteriolysins, and other unchristened agents—what a remedy this would be! One trouble about these antibodies is that they are too complicated and have to be manufactured by the body cells separately for each disease, and this the cells often cannot do; we can readily understand how the cells may find it difficult to manufacture the different complicated side chains to fit the corresponding links of each separate germ. Another fault is that being biological products manufactured by living cells and the bacteria which they attack also being living cells, the bacteria are able to make similar antibodies of their own. Thus we have the reciprocal antibodies, or so-called aggressins of the invading parasite being prepared to neutralize the antibodies of the blood; while in the case of a chemical compound the germ would be unable to manufacture an antidote so readily. The recognition of a hypersensativeness or an anaphylaxis which the body may develop for a substance, comes as a warning to the unreliability of some of nature's methods in this direction. How are we to know on administrating a remedy, especially a foreign blood serum, whether the patient can stand a double amount the next time or has developed such a hypersensativeness to it that another similar dose will kill him? We were led to believe that nature could develop enormous powers of resistance to any poison administered in increasing doses; what are we to think now of this dangerous reversion? How do we know now whether nature does not possibly at times make us hypersensative to the secretions of our own body cells and allow this rebellion of the tissues to cause all kinds of disagreeable idiopathic symptoms?

Where Compensation Fails.—We often admire the way in which one kidney does the work of two when the second is removed and how a small portion of lung will carry on the work of a widespread area destroyed by tuberculosis. This natural compensatory action, however, is by no means constant. In injuries to the eyeball we are familiar with the danger of sympathetic inflammation of the healthy eye. Sometimes, in fact, the ophthalmic surgeon can make of the injured eye a more useful one than the other, the victim of natural interference. In treating a wound involving a main artery of the leg or arm, nature calls various anastamosing arteries into service to form a circuit around the break in the bloodstream and to allow the circulation to proceed unimpeded. This is a wise provision and means the saving of a limb which at the present time the surgeon would have to sacrifice. Why, may we ask, does nature not have these anastamosing arteries instead of the so-called end arteries in vital organs so much more important than the limbs? If the dorsal artery of the thumb becomes plugged or divided, anastomosis with the princeps pollicis on the other side prevents this finger from suffering any loss of blood supply; on the other hand, if one of the ganglionic branches of the middle cerebral artery becomes plugged, nature is unable to do for the brain what it did for the thumb and apoplexy with death or worse is the result. The most vital spot of the brain is thus laid bare to a bit of natural negligence which even the smallest toe does not suffer. During starvation the different ways in which the body metabolism economizes in the food supply is often remarkable. Nevertheless, in a starving child, nature will allow the food to be used for the growth of the skeleton before supplying the vital organs dying of hunger, and the bones ignorant of their greed grow longer up to the very point of death. In anemia nature will allow the dupe to masquerade about as a fat and well-nourished specimen of mankind, when, in fact, he is starving to death; for while the blood cannot furnish enough oxygen to utilize the food eaten, the food collects in the tissues as useless matter unable to be touched by the neighboring cells which are dying of hunger.

As a final example of the many ways in which nature fails us as a skilled therapeutist, reference may be made to the act of childbirth. In face presentation when the chin rotates back against the promontory of the sacrum or in one of those nasty impacted shoulder presentations, further progress by natural means is impossible. The woman may

die in time of exhaustion or the uterus may even burst and make the end more hurried. How many pitiable mothers and newborn babies would be left to die were it not for the obstetrician's instruments? We are all familiar with the manner usually chosen by nature to relieve an extrauterine pregnancy and how this horrible accident may at any time without warning cast gloom upon our own family. Thus might be enumerated page after page the numerous blunders made by nature in treating disease. The examples drawn are all familiar ones, known to every physician; they can but recall others to his mind. Let us realize once for all that while it is human to err, it is also godly, and that in treating disease we do not have to follow too closely the rules laid down by a natural process which is more concerned with thinning out the whole race than with taking special pains to save individual members.

ETIOLOGY OF ADHESIONS OCCURRING ON THE LARGE INTESTINE.

By GOODRICH B. RHODES, A.B., M.D.,

CINCINNATI, OHIO.

JUNIOR SURGEON TO THE CINCINNATI CITY HOSPITAL AND EPISCOPAL HOSPITAL FOR CHILDREN.

Arbuthnot Lane, in 1908, called attention to certain adhesions in the intestinal tract and since then has in particular demonstrated the existence of a pathological kink in the ileum in the neighborhood of the cecum produced by these adhesions. His observations have been confirmed by many other surgeons, and Jackson[1] has further shown the existence of a veil-like layer of loose connective tissue overlying the ascending colon and noticeably constricting it. The existence of these bands gives rise to a definite symptomatology, varying in severity from the slightest degrees of intestinal indigestion, abdominal pain, or constipation, to the most grave conditions of anemia, autointoxication, and neurasthenia. Many cases of appendicitis which are unrelieved after operation have been shown to be due to the presence of these constricting bands, as proved by the subsequent cure of the appendicitis-like symptoms after the removal of the constriction.

Various explanations have been brought forward to account for the formation of these bands, among which may be cited the following: Lane[2] believes that the condition is caused by a ptosis of the cecum, with a subsequent thickening into adhesions along the lines of greatest resistance to the cecal prolapse. Binnie[3] regards the lesion as a primary pericolitis.

Hoffmeister[4] reports fourteen cases, in ten of which the *Trichocephalus dispar* was found.

Mayo[5] regards the formation of Jackson's membrane as due to embryonic causes, the bowel in these cases rotating late, and in its descent from the liver burrowing beneath the peritoneum, so that it comes to its final position with a membrane covering it. Chronic colitis has been urged as a cause by many, while Lennander[6] attributes it to an infantile colitis. It is conceded by all observers that cecal ptosis is a constantly found condition in these cases.

Adhesions or connective tissue bands of the intestinal tract caused by conditions other than inflammation or trauma occurring outside of the intestine are almost entirely confined to the large intestine, if we exclude the adhesions occurring in the upper abdomen produced by gastric or duodenal ulcer. Adhesions of the small intestine generally are readily explainable by inflammation in the neighborhood, such as tubal or ovarian disease, peritoneal irritation from tumor or trauma, appendicitis, or gall-bladder disease. On the other hand, if we study the reported cases of what might be termed idiopathic adhesions, we find that they are encountered with the greatest frequency and abundance in the cecal region and in that of the ascending colon.

We have, then, to consider a condition limited to a certain definite intestinal area, whose function, structure, and contents differ greatly from the area in which adhesion formation is not common. The greater portion of the solids in the intestinal contents, roughly about 90 per cent., is absorbed from the small intestine, and about 50 per cent. of the fluids. The remaining 50 per cent. of the fluids and only 10 per cent. of the solids are taken up from the large intestine, so that in the large intestine we have an entire change in the absorptive qualities of the gut, by virtue of which the soluble toxins are absorbed with greater readiness than in the small intestine. The character of the contents of the intestine now abruptly changes, as the reaction of the feces changes from alkaline to acid after passing the ileocecal valve. The semisolid mass now moves more slowly through the large gut than it did through the small intestine, thus affording a longer period during which the septic contents of the bowel are in contact with a given portion of the gut wall, which is busily absorbing the soluble toxins.

In general it may be said that the further down the intestinal tract we proceed the greater is the number of bacteria and the greater is their virulence. The climax is reached in the colon, where the colon bacillus is largely responsible for the acid reaction and where bacteria are exceedingly numerous, their toxins are most virulent and putrefaction is in progress.

The anatomical structure of the cecal region provides a focus where, in a cul-de-sac, a large portion of the intestinal contents can remain for a long period even in a perfectly normal gut; and in a cecum which has prolapsed and whose walls are atonic this period is very greatly increased.

In the normal intestine the passage of living bacteria or of their toxins through the intestinal wall does not occur, but, in the event of certain lesions occurring to the intestinal wall, or of interference with its vascularity, the passage of both has been demonstrated to occur with consistent regularity. Neisser and Hauser[7] have shown that in the normal intestine no bacteria can pass from the intestine to the blood lymphatics, but on the occurrence of artificially produced lesions of the intestines they have shown, as has also Beco,[8] that the passage of the colon bacillus into the circulation can be regularly made to occur. Their experiments were conducted by introducing artificial irritants, such as croton oil, powdered glass, or other irritants into the intestinal tract after a liberal feeding of colon bacillus cultures.

Klecki[9] and others have demonstrated that it is the interence with the venous return in a loop of strangulated intestine which is the basal cause of the gravity of the symptoms. The contents of the loop, he says, under these circumstances attain a very exalted degree of virulence, chronic passive hyperemia is induced, and there is a passage of the germs themselves besides their toxins through the intes-

tinal wall. He also had determined that the action of the toxins of a virulent colon bacillus is sufficient in itself to provoke a peritonitis. Oker-Blom[10] has shown that it requires a venous stasis lasting more than 72 hours to bring about an invasion of the peritoneal cavity by the germs themselves.

That there is a transmigration of organisms from the cecum and ascending colon is rendered very probable by a study of the reported cases of colon bacilluria. In the cases in which only one kidney was the seat of the infection, hence excluding a hematogenous infection, it is found in an overwhelming majority of cases to be the right kidney. The reason for this probably lies in the anatomical relationship of the right kidney and the ascending colon; Franke[11] has demonstrated a lymphatic connection between the ascending colon and the right kidney by which the bacteria can pass directly into the kidney from the intestine, provided that there is a slight lesion of the mucosa.

Some of the reported cases of these adhesions give a history of typhoid fever at some preceding period of life. This becomes an interesting point in view of Sanarelli's[12] investigations showing that the colon bacillus acquires an exalted degree of virulence in typhoid fever, due to the action of the typhoid toxin.

In view, then, of the observation of all the reporters that all these cases are accompanied by a ptosis of the cecum, it would seem a not improbable explanation of their production to assume the following sequence of events:

1. Cecal ptosis occurs, due to chronic constipation, with consequent dragging downward of the cecum by the weight of fecal contents or as part of the general visceroptosis.

2. Venous stasis now occurs, due to interference with the return circulation, lack of tone in the bowel wall, and irritation from the enclosed fecal contents, which now begin to manifest a very greatly increased degree of toxicity.

3. As a consequence of this stasis and the increased virulence of the bowel contents there occurs a penetration of the intestinal wall, first, by the toxins and later possibly by the germs themselves, after the condition becomes more aggravated.

4. The continued action of these slight amounts of toxins, exerted over a length of time results in the production of a new tissue formation.

5. This process constitutes, in effect, a vicious circle.

6. This process of connective-tissue formation, when localized in the neighborhood of the appendix in such a way as to constrict the appendix or to kink it, may be the cause of many cases of appendicitis of secondary origin.

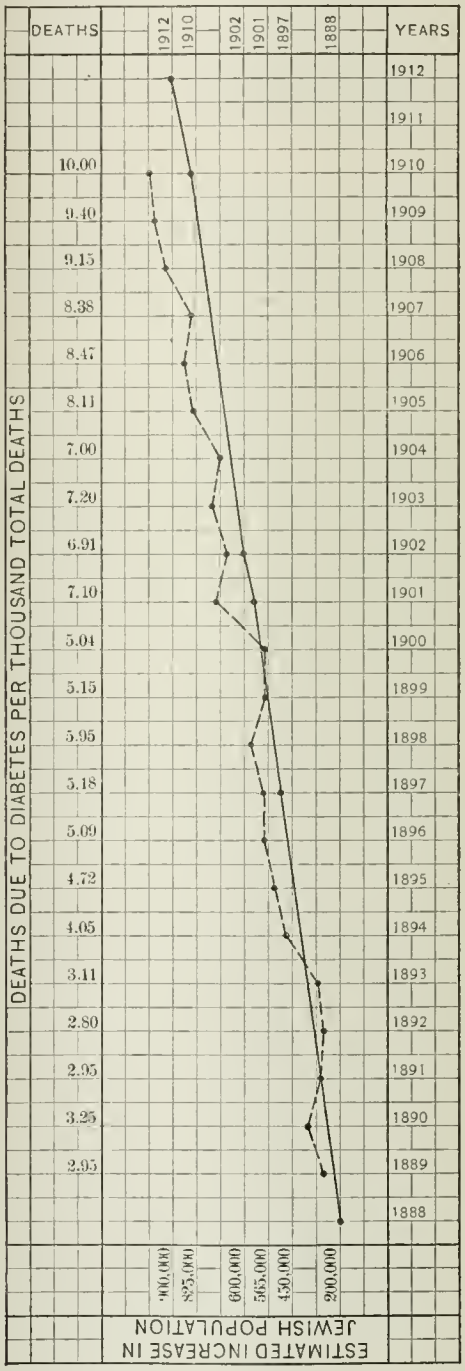
INCREASE IN THE DEATH RATE FROM DIABETES—A POSSIBLE EXPLANATION.

By J. G. WILSON, M.D.,

ELLIS ISLAND, N. Y.

ACTING ASSISTANT SURGEON, UNITED STATES PUBLIC HEALTH SERVICE.

The consensus of opinion is that diabetes is on the increase. So far as I have been able to ascertain, the data for forming such a conclusion are exclusively drawn from our large cities. There is no evidence that the disease is increasing among the



rural population. That diabetes is much more prevalent in New York City than it was twenty years ago is shown by an examination of the records of the Board of Health. In 1889, out of every 1,000 deaths from all causes in the Boroughs of Manhattan and the Bronx, 2.95 were ascribed to diabetes. In 1910 the deaths from diabetes in Greater New

York numbered 10 per thousand. Thus the death rate from this cause was increased more than threefold in a period of twenty years.

While much has been written concerning the essential nature of this disease, very little has been learned relative to the best means for its prevention. It is possible that this phase of the question will ultimately resolve itself into the methods of right breeding more than of right living. For the evidence seems to be accumulating that it is due to some hereditary defect, and that the tendency to become diabetic is accentuated by consanguineous marriages. Thus in the Johns Hopkins *Bulletin* for February, 1912, Nellis B. Foster reports from his own experience three instances of diabetes occurring in the brothers and sisters of the same family. He collected 130 cases of the same nature from the literature. In 24 of these it was specifically mentioned that the parents were likewise diabetic, and in several instances the affection had occurred in the same family for four generations. He quotes Weiselbaum as advancing the theory that in young diabetics an hereditary defect may exist in the islands of Langerhans, thereby rendering these structures more susceptible to toxic influences.

In an article published in the MEDICAL RECORD, November 17, 1900, Heinrich Stern noted the extreme prevalence of this disease among the foreign born. He said that out of a total of 202 cases in New York City for the year 1899, the death certificates showed that only 51 were native born. He likewise stated that the Jews suffered more than others from this affection and he attributed their greater susceptibility to the practice of inbreeding which obtains among them. Stern's statistics, compiled from the Board of Health records for the decade commencing 1889, showed a rise from 2.95 deaths per thousand in that year to 5.1 per thousand in 1899. I have gone over the records of deaths compiled by the Board of Health for the succeeding decade and have combined the results thus obtained with Stern's statistics in the accompanying chart. The fact that the death rates of the two decades are compiled, in the one case from the Boroughs of the Bronx and Manhattan alone before the incorporation of all the boroughs into Greater New York, and in the other case from the statistics after this incorporation took place, will not materially affect the result, for the reason that the comparison of the yearly increase is based on the relation of deaths from diabetes to deaths from all causes, and not on its relation to the number of inhabitants.

It occurred to me that perhaps the increasing death rate from diabetes in New York City might be dependent upon the increase in the Jewish population. I have endeavored to construct a curve of this increase, and to compare it with that of the death rate from diabetes. It will be seen that these two curves follow almost exactly identical lines. The estimated rate of increase of the Jewish population is of course open to some criticism because of the fact that the unfortunate method of classification by nationality instead of by race makes it impossible to obtain absolutely accurate vital statistics of the Jews in New York City. However, we have sufficient data to warrant the statement that the increase in Jewish population has been steady and progressive, and that in spite of a varying amount of immigration, the rate of increase has not been subject to marked fluctuations.

I have based my curve of Jewish increase upon Jacobs' statistics as given in the Jewish Communal Directory for 1912. Although he places the total number of Jews at a lower figure than the usually accepted one, his estimates are the most available for the purpose of comparison, because they represent the conclusions of one man alone, and are therefore not subject to the error which would inevitably arise were the figures taken from a great variety of sources. I have had to make one exception. The estimate of 200,000 for the year 1888 is my own. Between the years 1877 and 1897 I can find no estimate by Jacobs of the New York City Jewish population. In the former year he places the figure at 60,000 and in the latter at 450,000. If we draw a line backwards from this point on the chart to his estimate of 1877, it will intersect the year 1888 not far from the 200,000 point. That this is approximately correct is rendered all the more probable by the fact that in 1888 the Jewish Year Book placed the total number of Jews in the United States at 400,000. Although this is probably higher than the figures one would obtain by Jacobs' method, it nevertheless serves as a basis on which to calculate the New York City Jewish population for that year, for the reason that estimates of the total Jewish population in the United States from the same source show that in round numbers since the year 1888 about half of it has been in New York City. Consequently, I do not believe that the estimate of 200,000 can be far enough from the correct number to materially alter the close relation existing between the two curves of increase.

The striking correspondence of the two lines of increase as illustrated by the foregoing figures and the chart elucidating them is sufficient ground for at least suspecting that the increased death rate from diabetes finds its chief explanation in the increase of the Jewish population.

Purulent Pericarditis.—J. P. Parkinson and D. Drew report the case of a boy, aged 4½ years, who had an attack of pneumonia involving the bases of both lungs. The urine contained blood, pus, albumin and epithelial and blood casts with many pneumococci. The pneumonia ran an ordinary course, the temperature becoming normal at the end of ten days, and the signs in the right lung cleared up. The pulse-rate, however, remained the same and the heart sounds became muffled, but there was no friction sound or increase of the cardiac dullness. After a few days this latter sign appeared, and finally there was dullness up to the first rib and increase of dullness to the right. At the end of a week there was swelling of the face and some edema over the precordium. Two inches of the fifth costal cartilage were excised and there were evacuated 10 ounces of pus which contained pneumococci in pure culture. The recovery was uneventful, the signs of consolidation at the left base disappeared, and the urine became normal. There were now no signs of enlargement of the heart either clinically or by the *x*-rays. This case is interesting on account of the exceptionally good result of treatment. The boy now shows no sign of cardiac embarrassment, and the heart moves to and fro when the patient is put on one or the other side. Exploration of the pericardium ought not to be done with the needle, owing to the difficulty of diagnosis of fluid by physical signs. It seems better to open it deliberately, and in that way evacuate its contents, rather than to run the risk of puncturing the heart. In this case the diagnosis was fairly clear before operation, but that is frequently not the case.—*Proceedings of the Royal Society of Medicine.*

New York, October 12, 1912.

CLIMATIC INFLUENCES IN THE TROPICS.

SOME little time ago Major Woodruff advanced the view that the actinic rays of the sun are responsible for much of the morbidity and mortality which occur in tropical regions. Many arguments were brought forward in support of this theory and it was generally thought that Woodruff had made a very good case. In the *Military Surgeon* for August, 1912, however, appears a report of the Board for the Study of Tropical Diseases in the Philippines by Major Weston F. Chamberlain and Captain Edward Vedder, in which the conclusion is reached that it is by no means proved that the actinic rays of the sun are factors in tropical morbidity or that pigmentation of the skin is a protective effort on the part of nature against the chemical rays of the solar spectrum. According to their views the main causes of the troubles encountered in the tropics are infections, continuous heat, and high humidity. Subsidiary causes are nostalgia, isolation, monotony, and the excessive use of alcohol. Woodruff based his opinion largely on figures going to show that affections of the nervous system, including neurasthenia and insanity, are particularly likely to occur in the tropics as a result of excessive light stimulation. In opposition to this the report before us says that subsequent statistics do not confirm the view that nervous diseases are prevalent in the Philippines. The reports of the Surgeon-General of the Army for the years 1903 to 1909, inclusive, show that insanity and nervous diseases have been no more common among soldiers in the Philippines than among those in the United States. During the past five years, 1904 to 1909, there has been no material difference between the suicide rate in the Philippines and that of the United States. Neurasthenia has played but a small part in the morbidity of the Islands during these years. Yet the sunlight is the same as in the period from 1898 to 1902, and no special effort is being made to protect the men from the sun. More potent causes for the better health manifested by the soldiers in the Philippines are probably that the hardships, the bad sanitation, the poor food, the isolation, and the nostalgia of earlier days have been largely remedied.

Investigations were also made with regard to the relative resistance of blonds and brunettes in the tropics, and the conclusion was reached that pigmentation *per se* is not necessarily beneficial in the tropics, or rather that such has not been absolutely proven to be the case. From a consideration of the data available the authors of the report state that it appears that blonds are quite as well able as brunettes to withstand the influences of the Philippine climate for a period of two years and probably for a period of five and one-half years.

Without wishing to adversely criticise these several conclusions and while agreeing that the injurious effects of the actinic rays may have been exaggerated by Woodruff and other writers, it still seems that the authors of the report may have gone to the other extreme in too greatly minimizing the harmful action of these rays. The medical authorities of all tropical countries in which white folks reside have conceded that for them protection from the sun rays is at least strongly advisable if not absolutely necessary to conserve health. In India this is the consensus of opinion of medical men and of those who have lived in the country for a long time. Infections, heat, and high humidity are the main causes of disease affecting the white man in the tropics, but further and more convincing proof will have to be forthcoming ere the actinic rays of the sun can be regarded as a negligible quantity in the production of certain disorders. As for the protective influence of pigmentation of the skin in the tropics the question is more open. But, and this point must be especially emphasized, it is usually not until after several years' residence in the tropics that the healthy white man who lives in a regular and abstemious manner begins to deteriorate in health. Perhaps it might be more correct to say that the signs of deterioration do not show until after several years of residence. Of course, in the Philippines and elsewhere in the tropics in which the white man holds sway, good sanitation, pure water supply, and the destruction of insect life, especially of disease-bearing mosquitos, have been the principal means whereby diseases incidental to the regions have been warded off. Nevertheless, in the light of experience, it would seem that we are not yet justified in asserting that the actinic rays of the sun are not harmful to the white individual nor that pigmentation of the skin is not a protection against these rays. The subject is intensely interesting and the instructive report of Chamberlain and Vedder, though by no means conclusive, should stimulate further discussion.

THE DEAF CHILD.

THE medical inspection of schools has revealed the fact that deafness is not uncommon among school children. Dr. Helen Macmurchy of Toronto read a paper bearing on this question at the Sixth Congress of the American School Hygiene Association, which has since been published in pamphlet form. It is pointed out that it is often possible clinically to recognize the deaf child by inspection. Of course, this statement refers to the slight and medium degree of deafness. The deaf child seems to lack vital resistance. Besides there is something characteristic in the facial expression.

Children who are slightly deaf, that is, not so deaf that the condition is suspected by teacher or school nurse, are frequently greatly handicapped by the failure to recognize this condition. Dr. Macmurchy draws attention to the fact that in a perfectly quiet room the average normal hearing distance for a whisper is about twenty-five feet. A child that can hear a whisper only at five yards will not lose much education on account of this degree of impairment. Those who can hear a whisper only from three to five yards should sit on the front seats. Those who can hear a whisper only from one to three yards need special help, and should be placed in smaller classes with a teacher who will speak slowly and distinctly and will take special, individual interest. Those who can hear a whisper one yard away only, or less, should be in a small special class of ten or twelve and should learn lip reading. The above are simple, practical schoolroom tests. The congenitally deaf child should be taught lip reading at as early an age as possible, which will obviate to a great extent the handicap of mutism entailed by his affliction. The author summarizes the education of the deaf child as follows: (1) Teach the deaf child to speak. (2) Recognize the deaf child and secure his education. (3) Provide special teachers and special classes for the deaf child. (4) In large cities night classes for adults who are in danger of becoming deaf should be established in lip reading.

The plea of Dr. Macmurchy for the recognition of the slightly deaf child is pertinent and rational. Undoubtedly many children suffer from unrecognized slight deafness and are handicapped thereby. The praise of lip reading, the salvation of the deaf, is well deserved and the contention that the time has now come when medical inspection should carry the benefits of the method throughout the whole country is extremely well taken.

MORONS.

For some time past the daily press has contained many articles on the subject of eugenics and the feebleminded. Even the news items concerning domestic scandals and crimes of lighter or greater gravity have in certain instances sought to explain derelictions from the beaten paths of virtue on the ground of bad heredity. In this pseudo-scientific newspaper interpretation of bad acts the word "moron" is frequently encountered. Perhaps few of those who speak so freely of morons have a definite conception of the meaning of the word. It is derived from the Greek moros meaning a fool, and broadly speaking that is exactly what is meant when the word moron is properly used. In the technical sense in which the term is now employed by students of the feebleminded it is applied to those persons whose mental development is permanently arrested somewhere between the ages of eight and twelve years.

In the New Jersey Training School at Vineland out of 428 inmates 118 belong to the moron type. From an industrial standpoint these are useful members of the school. Those of the lowest grade of moron, that is with the mentality of a child of eight and nine years, are able to do errands, make beds, scrub, lay bricks, and care for the bathrooms. The middle-class morons, who are mentally ten years old, make good institution helpers. They do the routine work in a satisfactory manner. The high-grade moron is found among those who are classified as having the mentality of a child of eleven to twelve years of age. These do fairly complicated work with only occasional oversight. They use machinery and care for the animals of the place. But whatever the chronological age may be they never pass beyond the mental age of a child of twelve. They cannot plan. They lack initiative and are almost utterly devoid of creative imagination. Bereft of the care and oversight of an institution and turned out in the world to shift for themselves they soon find their way into the almshouses, jails, and reformatories. These are the born fools, who are inherently incapable of passing the mental age of childhood. Somewhere between the ages of eight and twelve years their intellectual development permanently ceases.

The Newer Conceptions of Meningitis Basilaris Posterior.

Until recent years all cases of posterior basic meningitis were regarded as tuberculous in origin. The English pediatrists, among whom may be mentioned Still and Thursfield, were the first to point out that most of these cases are really types of epidemic cerebrospinal meningitis. Gee and Barlow among others attributed some of the cases to syphilitic infection, while Gowers noted that in cases presenting cervical opisthotonos dating from birth the probable explanation is a meningeal hemorrhage at the base of the skull. This entire subject is exhaustively reviewed in the *Archiv für Kinderheilkunde*, August 13, 1912, by E. Hartje, who reports the history of a case which was apparently of non-infectious origin. He regards posterior basic meningitis not as a definite clinical entity but rather as a symptom-complex, the predominating manifestation of which in all cases is a pronounced cervical opisthotonos. The inflammatory process is confined to the meninges at the base of the brain, in the region of the medulla oblongata, the pons, and the cerebellum. The causes are various: in some cases bacteria, as the meningococcus or the pneumococcus; in other instances syphilis or traumatism may be the etiological factor; while in other cases the disease has been attributed to rheumatism, enteritis, and, as in the author's case, to the sudden action of cold. A pathological lesion that is common to all cases is the inflammatory closure of the foramen of Magendie and a consecutive internal hydrocephalus. Of the latter evidence is afforded by the presence of Macewen's sign or increased resonance on percussion over the parietal bones, which resonance Hartje compares to that of a ripe melon. Important points in the differential diagnosis of posterior basic meningitis from tuberculous meningitis are the facts that the former disease is of greater duration, recovery occurs in 16 per cent. of the cases, cervical opisthotonos is constantly present, optic neuritis and bradycardia seldom occur, nystagmus is a frequent manifestation, a retracted abdomen is rarely in evidence, while internal hydrocephalus is found in almost all cases. The opposite conditions, as is well known, generally prevail in the case of tuberculous meningitis.

News of the Week.

Tuberculosis and Poverty.—The New York Association for Improving the Condition of the Poor has recently completed a study of the causes of poverty in New York, from which the conclusion is drawn that tuberculosis is responsible for over 8 per cent. of the destitute homes in the city. Having previously found that sickness was the chief cause of dependency among the families in its care, the Association began an inquiry to determine which diseases are most prevalent, to the end that its preventive work might be better planned and more efficient. It was found that of 6,505 families applying for aid between October 1, 1911, and June 30, 1912, 1,605 were forced to do so on account of illness, and tuberculosis was found to be the disease responsible in 555 or 34 per cent. of these. Rheumatism forced 187 other families into dependency, and the remaining cases were classified as follows: Illiness attending childbirth, 161; kidney and heart disease, 156; pneumonia, 99; children's contagious diseases, 48; paralysis and epilepsy, 48; eye and ear diseases, 45; cancer and tumors, 44. The Association concludes from these statistics that the prevention of disease, and especially of tuberculosis, is a most important phase of the campaign against poverty.

Homicides on the Increase.—Statistics just issued show that the homicide record of the principal cities in the United States for the decade ending with 1910 exceeds that of any similar period in our history, and that the rate for 1911 is still greater. Whereas in the ten years ending with 1910 there were 9,672 homicides in all of the cities contributing statistics, making a rate per 100,000 of 6.9, in 1911 alone there were 1,300 homicides, giving a rate of 8.3 per 100,000. The highest rate is found in the Southern cities, Memphis, Tenn., having the unenviable record of 47.1 as the average rate per 100,000 for the decade, and of 63.4 per 100,000 for 1911, an increase of 16.3. In New York the rate per 100,000 for 1911 was 6.9 for Manhattan and the Bronx, an increase of 1.8 over the average for the ten years previous, and 3.6 for Brooklyn, a decrease of 0.6. The greatest increase in the 1911 rate as compared to the 1901-1910, occurred in Nashville, Tenn., where a difference of 21.7 was recorded, and the greatest decrease, 5.3, in Spokane, Wash. The statistics appear even more startling when compared with those of England and Wales, where the homicides average less than 1 per 100,000, and bring out an apparent disregard for human life in this country.

Health of the Canal Zone.—During the month of July there were in the Canal Zone a total of 42 deaths from all causes among employees, of which 32 were due to disease and 10 to violence, making an annual average rate per thousand of 10.34, which is lower than the rate for the same month of the two previous years, although in 1904 and again in 1909 still lower rates were recorded. The annual average death rate per thousand in the cities of Panama and Colon and the Canal Zone, including both employees and civil population for the month was 23.55. Among employees during the month the principal causes of death were as follows. Tuberculosis, 9; lobar pneumonia, 6; malarial fever, 2, and dysentery, 1. One case of yellow fever on a ship from Guayaquil, Ecuador, was isolated in Santo Tomas Hospital, and died there on July 14. With this exception no case of yellow fever, smallpox, or plague occurred on or was brought to the Isthmus during the month.

Must Furnish Sanitary Cups.—The Supreme Court of New Jersey recently handed down a decision upholdng the order of the Board of Public Utilities compelling all railroads furnishing water for their passengers to provide sanitary or individual utensils from which to drink it. Following the passage last year of a law prohibiting the use of common drinking cups in public places, a number of the railroads in the State removed the glasses from their trains, leaving it to the passengers to provide their own drinking utensils.

Plague in Azores.—The American Legation at Lisbon, Portugal, has reported to the State Department at Washington, the occurrence of several cases of bubonic plague on the island of Terceira, one of the Azores.

"Carrier" Books.—The school officials of Washington, D. C., have recently confiscated and destroyed 49,000 text books which had been found to be germ carriers.

Mushrooms Poison Party.—Twelve persons were poisoned, two of them seriously, from eating mushrooms at a party in Long Island City recently.

Visiting Physicians.—With each steamship arriving during the past week the number of distinguished physicians visiting in New York prior to the meetings of the International Congress of Hygiene in Washington has been increased. On September 17 a large delegation of German physicians, many of them accompanied by their wives and families, arrived in New York, and on the following evening were entertained at a reception given by the German Medical Society, at which Mayor Gaynor made an address of welcome. Excursions about the city were also planned for the visitors who thus visited the universities, the hospitals, the museums, and other places of interest.

Report of Milk Stations.—With the end of last month the Straus Milk Stations, New York, completed their twenty-first year of service, with a record of only one death during the summer among the 2,200 babies which have been supplied with milk from the seventeen stations. During the year 2,193,684 bottles of milk were dispensed and 1,326,100 glasses of milk were served in the parks and on the recreation piers. The summer stations have now been closed, but eight are kept open throughout the year.

Tuberculosis Day.—The National Association for the Study and Prevention of Tuberculosis has designated Sunday, October 27, as "Tuberculosis Day." Clergymen all over the country will be asked to speak to their congregations on the subject, and particularly to denounce from their pulpits the fake "cures" for consumption so widely advertised. It is estimated by the Association that the volume of business done by these fraudulent concerns amounts to more than $1,500,000, and that more than 500 such "remedies" of all sorts are now on the market.

Gifts to Charities.—By the will of the late Mr. Henry Rawley of New York, the New York Eye and Ear Infirmary and the Manhattan Eye and Ear Infirmary share equally in his estate, estimated at $11,400.

By the will of the late Mr. Richard C. Dale of Philadelphia the sum of $5,000 is bequeathed to the Children's Hospital of that city.

By the will of the late Enos R. Artman of Philadelphia a trust fund of $100,000 is created for the establishment of a home for poor and de-

serving Lutherans of both sexes. Should it, however, prove impossible to carry out this purpose, $10,000 of the sum named is bequeathed to the Philadelphia Home for Incurables for the erection of a memorial chapel. In addition, the sum of $5,000 is bequeathed specifically to the Home.

In the final accounting of the estate of the late John S. Kennedy of New York, the amount of his bequest to the Presbyterian Hospital of this city is given as $1,550,823.

Deaths in New York City.—During the week ending September 28 there were in New York City 1,194 deaths, as compared with 1,233 during the same week of last year. Of these 175 were due to diarrheal diseases and 308 were of children under one year of age. For the first thirty-nine weeks of this year the death rate was 14.51, for last year 15.70.

Personals.—Dr. Petacci of Rome, Italy, physician to the Pope, died at his home on October 1.

Dr. Charles S. Turnbull of Philadelphia has been reappointed by Governor Tener of Pennsylvania as a member of the Board of Trustees of the Home for Training Deaf Children.

Mr. Alexander H. Candlish, superintendent of the New York Post-Graduate Medical School and Hospital from 1894 to 1907, has been reappointed to that office after an absence of five years.

Dr. Allan McLane Hamilton of New York announces his removal to 36 East 40th street.

Dr. James G. Mumford, formerly of the Massachusetts General Hospital, has become superintendent and physician-in-chief of the Clifton Springs Sanitarium.

Seventh Congress of Balneology.—This congress will meet in Meran, Austria, on October 11 to 13, 1912, at which time honor will be done to Hofrat Winternitz, president of the confederation for many years. Delegates from the Austrian, Hungarian, German, and Swiss societies are expected to be present.

Lectures at the Post-Graduate.—Prof. H. Strauss of the University of Berlin will lecture, in German, at the New York Post-Graduate Medical School and Hospital, Second avenue and 20th street, on Monday, October 14, at 4 P.M., on "Gastric Secretion from the Therapeutic Point of View," and at the same hour on Tuesday, October 15, on "The Method and Purpose of Dechlorination in Nephritis."

Prof. C. von Noorden of the University of Vienna will give a series of lectures, in English, at the Post-Graduate on "New Aspects of the Pathology and Treatment of Diabetes," and on "Diagnosis and Treatment of Nephritis," beginning on Tuesday, October 29, at 4 P.M., and continuing for four consecutive days at the same hour. Cards of admission to all these lectures will be issued upon application.

Abuse of Medical Charity.—At a meeting of the Physicians League of Brooklyn, N. Y., on September 27, a very interesting discussion as to the abuse of medical charity occupied the evening and as a result a committee was appointed to tabulate the more conspicuous abuses of medical charity and the most promising of the suggested remedies therefor, so that these could be acted upon at the next meeting, which will take place at the County Medical Society Building on October 18.

Utah State Medical Association.—At the annual convention of this association held in Ogden on September 24 and 25, the following officers were elected: *President,* Dr. Andrew J. Hosmer, Salt Lake City; *Vice-President,* Dr. Richard A. Pearse, Brigham; *Secretary,* Dr. William Brown Ewing, Salt Lake City; *Treasurer,* Dr. Howard P. Kirtley, Salt Lake City. The next annual convention will be held in Salt Lake City. The association went on record as favoring the sterilization of habitual criminals, epileptics, imbeciles, and the insane, as approving of the Owen bill and condemning the Senators from Utah, who had failed to support it, and also as condemning the telephone service in Utah, which it declared to be inadequate and intolerant, demanding immediate attention of the courts or of the next legislature.

Ohio County (W. Va.) Medical Society.—At the annual meeting held in Wheeling on September 16, the following officers were elected: *President,* Dr. Jacob Schwinn, Wheeling; *Vice-President,* Dr. John T. Thornton, Wheeling; *Secretary,* Dr. Jonathan Edward Burns, Wheeling; *Treasurer,* Dr. R. McC. Baird, Wheeling.

Obituary Notes.—Dr. Frank Judson Parker of New York, a graduate of Yale University, Medical Department, New Haven, in 1898, a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the New York Ophthalmological Society, the American Ophthalmological Society, and the Medical Progress Club, assistant attending surgeon to the Manhattan Eye and Ear Hospital, ophthalmologist to the Presbyterian Hospital Out-Patient Department, and consulting ophthalmologist to Seton Hospital, the New York Orphan Asylum, and the Greenwich Hospital, Connecticut, and attending physician to the Blind Babies' Home, died in the Presbyterian Hospital, New York, on October 2, aged 39 years.

Dr. Leon M. Nugent of Wauwatosa, Wis., a graduate of Marquette University, Medical Department, Milwaukee, in 1908, and a member of the Wisconsin State and Milwaukee County Medical Societies, was killed in an accident on September 7.

Dr. Henry Fiske Leonard of Boston, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1880, and a member of the Massachusetts State and Suffolk County Medical Societies, died in the Worcester State Hospital after a long illness on September 25, aged 54 years.

Dr. Thomas Anderson of Watertown, Mass., a graduate of the Chicago Homeopathic Medical College in 1878, died at his home on September 18, aged 75 years.

Dr. Albert Wood of Worcester, Mass., a graduate of the Harvard Medical School, Boston, in 1862, a veteran of the Civil War, and a member of the American Medical Association and the Massachusetts State and Worcester County Medical Societies, died at his home on September 26, aged 79 years.

Dr. Daniel B. Street of Washington, D. C., a graduate of the Georgetown University School of Medicine, Washington, in 1874, and a member of the Medical Society of the District of Columbia, died at the home of his daughter in Moose Jaw, Saskatchewan, Canada, after a short illness, on September 18, aged 70 years.

Dr. Albert Gallatin Jones of Lexington, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1862, died at his home on September 18, aged 85 years.

Dr. Francis M. Daily of Beloit, Kan., a graduate of the College of Physicians and Surgeons,

Keokuk, Iowa, in 1878, and a member of the American Medical Association and the Kansas State and Mitchell County Medical Societies, died at his home suddenly on September 14, aged 57 years.

Dr. Thomas A. Hays of Louisville, Ky., a graduate of the Hospital College of Medicine, Louisville, in 1875, died at his home after a long illness on September 17, aged 57 years.

Dr. Thomas J. Mitchell of Jackson, Miss., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1852, a member of the American Medical Association and the Mississippi State and Hinds County Medical Societies, a surgeon in the Confederate Army during the Civil War, and for thirty-two years superintendent of the Mississippi State Insane Hospital at Jackson, died at his home on September 16, aged 82 years.

Dr. A. W. Gould of Cleveland, Tenn., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1877, died after a short illness on September 18, aged 75 years.

Dr. Francis H. Fisk of Nashville, Tenn., a graduate of the Eclectic Medical College, Cincinnati, Ohio, in 1857, died at his home on September 13, aged 75 years.

Leonard W. Williams, M.A., Ph.D., instructor in comparative anatomy in the Harvard Medical School, Boston, while attempting to operate an electric elevator in one of the medical school buildings on September 26, was caught between the walls of the shaft and the car and was crushed to death. Dr. Williams, who was forty years of age, was a graduate of Hanover University, and had received degrees from Princeton and from Brown Universities.

Dr. Daniel R. Ambrose of New York, a graduate of the New York University Medical College in 1868, died in the Metropolitan Hospital, Blackwell's Island, on October 1, aged 77 years.

Dr. Joseph Hasbrouck of Dobbs Ferry, N. Y., a graduate of the New York University Medical College in 1869, a member of the Board of Health of Dobbs Ferry, and of the New York Academy of Pathological Science, and attending physician to the Dobbs Ferry Hospital, died suddenly on October 2, aged 73 years.

Dr. George H. Knight of Lakeville, Conn., a graduate of the New York University Medical College in 1881, a member of the American Medical Association, the Connecticut State and Litchfield County Medical Societies, and physician in charge at the Connecticut School for Imbeciles, Lakeville, formerly a member of the Connecticut Legislature, and surgeon-general on the staff of Governor McLean of Connecticut, died on October 4 of heart disease as he was about to address a political meeting endorsing him as the Republican nominee for Congress, aged 56 years.

Dr. George Gleim of Lansdowne, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia in 1865, and a member of the Pennsylvania State and Delaware County Medical Societies, died at his home on September 21, aged 68 years.

Dr. William A. Neal of Elkhart, Ind., a graduate of Rush Medical College, Chicago, in 1857, and a member of the Indiana State and Elkhart County Medical Societies, died recently at his home, aged 76 years.

Dr. John Cowden of Petersburg, Tenn., for half a century one of the leading physicians of that town, died at his home on September 20, aged 76 years.

Correspondence.

YALE COLLEGIATE SCHOOL AND HOSPITAL IN CHINA.

To the Editor of the Medical Record:

Sir:—The Yale Hospital in Changsha, Central China, needs two men for its staff in the summer of 1913. Men who have recently completed their interneship in an American hospital and who wish for a large practical experience in medicine or surgery will find this a splendid opportunity. The last appointee writes that he has had three times as much experience in his first year there as he would have had in the United States.

We have an up-to-date surgical equipment with a great deal of major surgery, and a large medical clinic with a good laboratory for research work. Our old hospital has forty beds, but we are soon to begin the construction of a fine new plant.

The places are open for either a temporary or a permanent appointment, preferably the latter; and men who have received a Yale degree will be given preference. I shall be very glad to hear from interested men who will state their qualifications and shall be glad to give them full information about the conditions of appointment.

Edward H. Hume, M.D.
Physician in Charge.

156 Fifth Avenue, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE ACT; SCHEMES FOR A STATE MEDICAL SERVICE; GRIEVANCES OF NURSES—TUBERCULOSIS, EFFECTS ON RACE; HOUSING, OR OTHER CAUSES—CONFERENCE OF HOSPITALS ASSOCIATION.

London, September 20, 1912.

The Advisory Committees of the Insurance Commissioners are meeting today to consider the regulations to be issued for the administration of the medical benefit, and it is understood that a committee of medical men will be present. There was a preliminary meeting yesterday and on Wednesday of those medical members who did not retire from the Advisory Committee. A draft of the proposed regulations is said to have been prepared and will, of course, be considered and equally, of course, may or may not be adopted by the Commissioners. It seems quite time the regulations proposed should be decided on, so as to give the profession an opportunity of examining them before their final adoption. Certain minor points are reported to have been agreed upon, but not the rate of remuneration to be recommended to the government to offer. As to this, it is possible the Cabinet will consider the proposition at the meeting next month. They ought by that time to be under no misapprehension as to the feeling of the profession. During the week some new points and proposals have been freely discussed in the press, and that in regard to the interests of the public as well as of medical practitioners.

When Mr. Lloyd George held out a sort of threat to organize a State Medical Service he only raised a smile, for he must himself have known that he could not in a few weeks provide education for a new generation of doctors to displace those in existence. There has, nevertheless, continued a good deal of discussion as to whether such a scheme might eventually be arranged and what would be its effect on the public and at the same time on the

profession. The British Medical Association, or rather its officials, have favored such a plan, and this week is submitting to its branches a "model public medical service scheme" for providing persons insured under the act and others with medical attendance. No little time and trouble must have been spent by the committee who prepared the scheme, which consists of thirty-one clauses and is based upon a capitation system of payment. An alternative model based upon payment per attendance is also submitted. Many points affecting both doctors and patients are laid down, and rules which will be generally thought appropriate. But there is one weak point—the proposal tends to strengthen the British Medical Association and hand over all power to its officials. So much is the "model service" a duplicate of the association that anyone violating a rule or resolution of the branch (or division) with reference to conduct detrimental to the profession may be expelled from the service. Can it be imagined that the profession will allow the British Medical Association or one of its divisions to vote forthwith the ruin of any gentleman who offends its officials? The British Medical Association is, after all, only a trade union in its constitution and proceedings. The universities and licensing corporations cannot permit their degrees and diplomas to be liable to cancellation by a trade union.

Other schemes have been propounded for the formation of a State Medical Service and are being discussed by the public press. All necessarily include the discredited system of contract practice. To most practitioners this is exceedingly objectionable, but there are some who hold that, organized on the plan of the civil service, it would work well, and indeed such a scheme has long been successful in India. But the conditions there are very different.

Those who advocate a State system say, "Look at the army or navy, or even at the police force." Comparing disease to an invader, they declare we can no more eradicate it by a private adventure force than conquer the enemy by an unorganized mob. They say everyone can have the free choice of his doctor and the wealthier classes can employ the unattached practitioners, who cannot all be superseded. Then they would give good salaries and pensions to the State doctors and the public would be benefited by the linking up with hospitals and dispensaries, which is recommended as an essential part of a complete scheme.

Turning to the other side of the question, the opponents of State interference denounce all the schemes as rank Socialism, and assert, apparently in accordance with the facts, that the mass of the profession is opposed to anything of the kind. They argue that all contract practice is essentially bad, and, although to some extent necessary, as for the army and navy, it is desirable to confine it within the narrowest possible limits. Admitting that the contract system has succeeded as to medical officers of health, they urge that this service is special and very restricted, but pointing to the poor law service, which is extensive and a nearer approach to a general scheme, they ask, has that raised the status of the profession, or the contrary? It is certain that poor law appointments do not attract the best men and, as a rule, patients who can pay something rather avoid the "parish doctor." Would not the same feeling prevail in favor of the independent against the State doctor? Then the cost of the Socialist schemes might give pause to Parliament. Even Mr. Lloyd George told the profession it would be impossible to provide funds on the terms that had been named, but these later schemes would entail a much vaster expenditure. The existing system of independent practice has satisfied the public for generations, and only the restlessness of revolutionaries desires to alter it. It is said that the Government can crush the profession completely, scattering ruin throughout. But it is doubtful, and it is pretty certain the public would not permit such destruction for political ends of a class toward which it has only good will. Moreover, it is quite certain the Government could not suddenly supplant 20,000 educated practitioners by qualified competitors.

The grievances of nurses under the act were illustrated yesterday at a Harvest Festival given by the Lord Lieutenant of Berks to 500 visitors. He said that at the Royal Berks Hospital, of which he is president, whenever a nurse is ill she receives every possible care and attention. Yet both she and the hospital were compelled to contribute under this act, and their money would be thrown into the melting pot to help some other cause.

The effect of the anti-tuberculosis campaign on the race is the subject of a contribution to a morning paper extending over about two columns. The writer, who only appends initials (C. E. W.), refers to the ravages which the bacillus makes in any community in which it may be introduced, and to its hardiness and the difficulty of eradicating it. Yet he sees we have acquired, through ages of suffering, an immunity which has enabled us to build up a sturdy race, though persons whose immunity is imperfect still fall victims to the microbe. We cannot exterminate this nor can we exclude all sources of infection. What then, he asks, must happen? And answers, retrogression of racial immunity and another more immune race will supplant us as we are doing the Australians and New Zealanders, and by the same means—the tubercle bacillus. The writer seems to be an extreme eugenist and opposed to the campaign against tubercle as scheming to save infected or susceptible persons who will produce a more susceptible generation, involving greater suffering in the distant future, which, he says, is hardly a moral attitude. He sees only one hope that the campaign will not decrease the standard of immunity to too great an extent before natural selection, under some favorable concatenation of circumstances, intervenes and eliminates many of the susceptible persons who have been preserved. The experiment will be tried, but he thinks the more successful it proves the greater will be the number of susceptible children in the next generation, and they and the next will suffer in proportion.

When noticing, in my letter of the 7th inst., Sir J. C. Browne's address, I referred to his criticism of Prof. Karl Pearson, who repudiates the notion that "housing is at the root of tuberculosis." The professor has since taken exception to the quotations made, and so it may be only fair to refer to his reply, especially as he avers that the speech of Sir J. C. Browne is typical of the spirit against which he is fighting. He says we have no evidence to indicate why the tuberculous are found in poorer tenements, whether it is a result of a postphthisical economic failure of the bread winner or a prephthisical inferiority in physique or mental efficiency, leading to economic and constitutional breakdown. He remarks that one blames housing;

another, occupation; a third, constitution; another, contact in schools; and yet another, bovine infection. So he would discard opinions and try to find how these or other factors contribute to the observed result. Two points at least, he says, are obvious: (1) The death rate from phthisis was falling long before extreme sanitary activity became fashionable; (2) it has not been falling at an *accelerated* rate during the past fifteen years, when we have known all about the bacillus and have started sanatoria and dispensaries and proclaimed the "fight against tuberculosis." He would cry, "Light; more light," but would add, "Less talk; much less talk." He complains that Sir James made no attempt to meet his figures as to parental health and habit being 50 per cent. more influential on infantile death rate and delicacy than employment of women or housing of parents.

The third annual conference of the British Hospitals Association was opened yesterday at Birmingham. The Lord Mayor welcomed the assembly to his city and expressed a hope that the Government would realize the strong opinion of the public in favor of the doctors being well paid. They wanted, he said, no strict calculations as to what was the lowest living wage for a well educated medical man. Much fear was expressed that the Insurance Act would inflict injury on hospitals, and some speakers thought it might lead to the interference or even the control by the State.

About 400 members of the Sanitary Inspectors' Association assembled at the opening of their conference last week, at the University of Sheffield. The Report showed continual growth, the present membership being over 1,600. A 10th centre has been established in Bombay and the 11th in the Transvaal. The President, Sir Jas. Crichton Browne, delivered his address on Tuesday—subject "A Plea for Sanitation." He said however they might squirm under the vexatious requirements of the Insurance Act and its multiplication of officials, they could approve of the sanatorium benefit. But he admitted that before immense sums were spent on buildings it should be borne in mind that for half a century the phthisis mortality had fallen nearly 60 per cent., and if that could be maintained the disease would disappear in two or three generations—and the fall was due to sanitation in the widest sense. If sanatorium treatment alone were trusted or if funds were withdrawn from sanitation disappointment would result. The sanatorium was the ambulance to carry the wounded from the field—sanitation the guns and ammunition. Some said the tubercle bacillus is losing its toxicity—it is as venomous as ever. Others said the decline of tuberculosis was due to the survival of the fittest, those most susceptible having been killed off—a specious but unproved hypothesis. Many of the most gifted had been swept off by the disease and to rely on the gradual elimination of the weaklings was to sacrifice the most uplifting elements of human nature. After all housing was at the root of the question as doctors best knew and a few benevolent visitors. Institutional segregation for advanced cases giving off infection is an educational agency, but prevention is better than cure and a large proportion of cases can be prevented by reformed housing and others successfully treated in dispensaries. The campaign against tubercle must begin with babies. It must extend to cows and cowsheds. Also to schools, factories, workshops, offices and banks. All are at times incubation chambers for the bacilli. The eugenists were disappointed with sanitation and Prof. Karl Pearson assailed, and to his own satisfaction demolished, the most cherished sanitary beliefs, but it was as easy to question the existence of Sheffield, where he was speaking, as to doubt that alcoholism, one-roomed tenements, back-to-back houses, artificial feeding and other conditions had not swollen the rate while lessening any of these had diminished it. Sanitation ought to have preceded education, and the children fed before being crammed with knowledge. Eugenics offered no help to the education problem and if controlling the feeble-minded prevented the birth of a few imbeciles the effect would be trifling and the thorough-going theorist would still consign millions of people to the death chamber.

An international dental exhibition has been opened under the auspices of the Incorporated Dental Society. Instruments and appliances of all kinds connected with dentistry and illustrating its progress are on view. One specimen is supposed to be more than 100 years old, when dentures were carved in solid ivory and were very expensive. Artificial teeth are now made of all shapes and of many colors. British manufacturers supply various countries according to their tastes. Eastern peoples who chew betel nut want them to match the stains produced by that habit. In some parts the darker the stain the more is the native admired. The Parisians and some others admire white, and various shades between find favor. The shape, too, varies with fashion. Thus in some parts along the Mediterranean shores long, grayish teeth are in demand, while those exported to Sweden and Norway are lighter in tint and shorter.

THE SIXTH INTERNATIONAL CONGRESS OF OBSTETRICIANS AND GYNECOLOGISTS.

(From A Special Correspondent.)

INTEREST OF THE EMPRESS OF GERMANY IN THE CONGRESS — SOCIAL FUNCTIONS — PRESIDENT'S ADDRESS—VALUE OF INTERNATIONAL CONGRESSES —ELECTION OF DR. GOFFE—NEW YORK CHOSEN FOR THE NEXT CONGRESS—REACTION OF THE PERITONEUM TO SURGICAL INTERFERENCE AND BEST MEANS OF CONTROLLING IT—THE SURGICAL TREATMENT OF UTERINE HEMORRHAGE IN PUERPERAL CASES—UTERINE PROLAPSE—OPERATION FOR CARCINOMA UTERI.

BERLIN, GERMANY, September 9-13, 1912

THE Empress of Germany has attracted the attention and admiration of all Europe by her devoted interest in the hospital care and treatment of women and children. It was a pleasant augury of success, therefore, when the invitations to the Congress announced that it would have the patronage of her Most Gracious Majesty the Empress and Queen. This was the first meeting of the Congress on German soil, and her loyal sons were zealous in their efforts to make sure that the hospitality of their capital city should at least generously equal that of any of her predecessors. The arrangements for the meeting, both scientific and social, were most elaborate, generous, and appropriate. The Imperial Government courteously granted the use of the Herrenhaus (upper house of the Prussian Diet) for the scientific sessions, and the first general reception of the members of the Congress and of the accompanying ladies was given in its festival halls and garden. German custom in the

varied phases of life, from the most important government functions to the simplest domestic life, always makes ample provision for eating and drinking. It was, therefore, no surprise to find the Herrenhaus provided with facilities for this function.

The assembly room proved to be the inner sanctum of the great building, a room encased on all sides and on its ceiling with panels of yellowish brown wood and furnished throughout with the same, even to the desks and statuary. Here the Congress opened with a call to order by the President, Professor Bumm of Berlin, who proceeded to deliver the presidential address. He emphasized the value of international medical and surgical congresses as a means of disseminating the latest and best achievements of its members, submitting them to the judgment of its fellows, and sifting out what is valuable. By them is given the opportunity of studying the personality of men, their animating motives, and the soundness of their conclusions. Men like McDowell of America, the first ovariotomist, and Semmelweiss, who discovered the true nature of puerperal fever, were not appreciated by their contemporaries and had to battle long and hard for their ideas. In our custom of international conferences those men would not have been obliged to go through such ordeals. Every congress cannot announce an epoch-making discovery, but the stimulant to new and better work never fails. In a large sense, also, they make for understanding between peoples of different nationalities and the peace of the world.

Then followed the formal announcement of the program of the meeting. The Organization Committee, which had been in session for two hours, reported that a most cordial invitation had been extended to the Congress by the united gynecologists and obstetricians of all the national organizations of the United States and Canada to hold the next regular meeting in New York in 1915. The committee recommended the acceptance of this invitation and nominated Dr. J. Riddle Goffe of New York as President. Both recommendations received the unanimous approval of the Congress. Dr. Goffe in accepting the presidency expressed his appreciation of the signal honor that had been so unexpectedly conferred upon him and upon his country. There is no city, no nation, to which this Congress comes without bringing an irresistible impulse to renewed effort and better work. It is a great engine of progress. The speaker was therefore especially happy that his country was to be favored with this great uplift. The Congress could rest assured of a most cordial welcome and the best hospitality the country affords. Personal assurances were given by delegates from all the different nations that they were eager to come to America to see our hospitals, our laboratories, and our work.

The program of the Congress embraced two principal themes for discussion and one day's session for miscellaneous papers. The first theme was "The Reaction of the Peritoneum to Surgical Interference and the Best Method of Controlling it." This was presented in twelve elaborate papers, followed by a general discussion.

H. Brouha of Belgium said: (1) Mechanical irritation of the peritoneum is injurious; it should be reduced to a minimum, but should not be restricted to a degree that interferes with complete hemostasis. (2) The peritoneum should be dry cleaned; washing with solutions is more dangerous than useful. (3) The use of rubber gloves is a great advance. Masks and chin bandages for operator and assistants, the supervision of their hair and teeth, and the use of linen caps are essential. Unnecessary conversation is prohibited and also the wearing of a beard. (4) Leave the peritoneal serosa entire if possible; stumps and raw surfaces should be covered and hemostosis fully secured, (5) When drainage is necessary gauze is preferable to rubber, glass, or silver tubes. L. Meyer of Copenhagen said that dry cleaning is preferable except in cases of the escape of feces, particles of food, etc. A very strict cleaning especially for blood is not necessary. Drainage is useless if the process is not quite limited and shut off by adhesions. The "peritonization" of surfaces not sufficiently covered is necessary in order to prevent undue fixation or too great dislocation of intestines. Larger open spaces in the cellular tissue and raw surfaces of the pelvis are best drained by gauze through the vagina. K. Franz of Berlin remarked that every peritoneal wound is to be considered bacteriologically infected. It is impossible to conduct an operation entirely free from germs. In the majority of cases these are harmful, being either too few in numbers, lacking virulence, or being destroyed by protecting forces of the peritoneum. Strictest asepsis was necessary in order to obviate the above and protect against virulent varieties. We should use rubber gloves, paint the skin with iodine, and cover it with sterile cloths. The principal danger now is from the patient, necrotic ovarian tumors, decayed myomas, adnexal infection, germs from the cervix uteri, the bladder, and especially the intestines. The absorption of bacteria into the lymph system occurs most readily on the diaphragm. Large quantities of saline solution introduced into the peritoneal cavity or circulatory system are apt to dilute too greatly the bactericidal properties. Absorbable ligatures and suture material should be used. Make as small incisions as possible. Transverse incisions are better than longitudinal. In suitable cases vaginal operations are preferable to abdominal. As far as possible cover all peritoneal wounds. Cauterization of these surfaces is not advisable. Such eschars predispose to infection. Drain the peritoneum as seldom as possible. In pus cases drain with gauze by vagina if possible; otherwise use a Mikulicz drain."

H. Macnaughton Jones, London, presented a report compiled from the views of sixty-seven leading gynecologists of the United Kingdom. He said that lavage, tamponade, and drainage are at best necessary evils. Dry treatment is better than moist treatment and absorbable sutures and ligatures are best. A few, fearing tetanus from catgut, use silk exclusively. Asepsis is secured only by a complete hemostasis and careful peritonization of all exposed surfaces. The use of cyllin as a disinfector of the bowels after operation is recommended. P. Licine, Paris, said that one should choose wisely the moment and extent of operation. The use of sterile rubber gloves is advised. One should peritonize all eroded surfaces when possible. Resinilli of Florence, Italy, said that one should isolate as far as possible the field of operation. Rest and immobility of the parts after operation are important. Moist, warm compresses and sponges are preferable. Silk is preferable to catgut. The former can be sterilized with greater

certainty. Rubber gloves should be used and iodine should be applied to the skin. Operate rapidly, using incisions that are transverse and as short as possible. Use gauze strips packed concentrically for isolation of infected areas; remove them gradually. Secure perfect hemostasis, cleanse the cavity of all blood and other liquids. Injections of camphor oil are recommended.

B. J. Kouwer of Utrecht said that the operative technique is far more important than antiseptic measures. Drainage and tamponade are to be avoided. Do not stretch the abdominal wound by too strong reactors. The cellular tissue is more subject to infection than the peritoneum. Josef Lovrich of Budapest believes that one should examine the patient carefully and know her resistance before operating. Prepare her for the ordeal. Use catgut exclusively in the peritoneal cavity, and iodine for the skin. Never use the high Trendelenburg position. Ligate arteries singly. Peritonize all raw surfaces. For drainage one should employ iodoform gauze through the vagina when possible. In the latter case the gauze should be removed in seven days. Dry sponging is preferable. Open the bowels in twenty-four hours. Patient takes any position in bed that is desirable, but early getting up is not encouraged. Wertheim of Vienna emphasized the following points: (1) Avoid mechanical, chemical, or thermic injury. (2) Do the cleanest, dryest work possible, and cleanse the cavity of all tissue material. (3) Cover all defects of peritoneum with serosa. (4) Drain subperitoneal spaces with gauze *per vaginam,* if possible.

Herman J. Boldt of New York, in a brief paper, described his method of suturing and bandaging the abdominal wall in laparotomized patients, and his practice of allowing convalescent patients to sit up early. This paper was favorably received.

Oskar Beuttner of Switzerland presented a summary of his conclusions in response to individual questions. Twenty-nine colleagues use moist asepsis and 21 use the dry method with no apparent difference in results. Forty-five colleagues emphasize the importance of guarding the peritoneum from all injury; 5 think this care ought not to interfere with the rapidity in completing the operation. All practice careful "peritonization" of denuded surfaces; 44 wear rubber gloves; 6 indifferently, usually for self-protection in septic cases; 17 use catgut exclusively; 8 use silk or linen; 25 silk or catgut indifferently. For closing peritoneum and in septic cases iodine catgut is preferred. In clean cases and for intestinal suture fine silk is preferred. Fifteen use camphorated oil in the peritoneum to avoid adhesions; 35 do not. Most of the colleagues use a Mikulicz drain; some use strips of gauze or a cigarette drain; 37 emphasize their preference for vaginal drainage, especially after the Wertheim cancer operation. All insist upon the importance of the strictest hemostasis.

Racasens of Madrid believes that the essential elements of success in abdominal and pelvic operations are a rigorous aseptic technique, rapidity, the strictest hemostasis, and peritonization of denuded surfaces. Klotz of Tübingen called attention to the value of the infundibular extract of the pituitary body as a valuable therapeutic agent for the treatment of peritonitis. When injected in conditions of failing blood pressure it restores the latter to the normal for a prolonged time. Two cases are reported in which the extract was used successfully, resulting in the saving of life. Hochne of Kiel advocated injections of camphorated oil into the peritoneal cavity as a prophylactic measure in septic cases for the prevention of septicemia and toxemia. This injection can be repeated at the close of the operation if the irritative reaction from the first does not seem sufficient. In the Kiel Frauenklinik this treatment has been applied successfully in 250 cases in which the peritoneum was likely to be infected. No camphor intoxication or secondary adhesions have been noted. Hannes of Breslau advocated in desperate cases abundant gauze drainage of both the pelvis *per vaginam* and of the abdomen by the Mikulicz tamponade.

The second theme was "The Surgical Treatment of Uterine Hemorrhage in Puerperal Cases." Ten full papers were read and twenty-three participated in the discussion. Couvelaire of Paris presented concisely the present doctrines and practices of French accoucheurs respecting the surgical treatment of retroplacental hemorrhages and those due to insertion of the placenta on the inferior segment. This includes: (1) Direct surgical hemostasis by hysterotomy; (2) hemostasis realized automatically by the uterine muscle after evacuation of its contents by hysterotomy, abdominal or vaginal. French accoucheurs, in the treatment of placenta previa, remain faithful to purely obstetric methods. These are wide rupture of the membranes, and eventually the introduction into the widely opened cervix of the incompressible ball of Champetier de Ribes, or in default of the ball, simple turning, without extraction (Braxton Hicks.) The complete statistics recently published at Paris, Lyon and Toulouse render it possible to form an exact idea of the results obtained by this method. For women bleeding from a vicious implantation of the placenta the mortality during the past twenty years has been about 4 per cent. Infection and violence during evacuation of the uterus are responsible for three-fifths of the deaths. The extremely small risk of death from hemorrhage (1.2 per cent.) does not justify cesarean section, premature delivery, or the systematic practice of hysterotomy during labor. The fetal mortality oscillates with the obstetric methods between 44 per cent. and 60 per cent. Retroplacental hemorrhages and complex dystocia, cases in which there is some obstacle to delivery (contracted pelvis, fibroma, cervical cicatrices), and cases in which the previous methods have failed or in which infection or extreme anemia are present, may demand transperitoneal cesarean section.

E. P. Davis of Philadelphia opened the general discussion of this theme with a brief but concise and convincing paper in which he advocated, in appropriate cases, abdominal section and control of hemorrhage by manual compression of the abdominal aorta. Ph. Joung of Göttingen said that myomata causing hemorrhages during pregnancy are always situated in the cervix, and must be removed. When abortion occurs hysterectomy is indicated to prevent infection. Carcinoma uteri indicates prompt radical hysterectomy. Perforating lesions demand suture or hysterectomy. In extreme acute hemorrhages compression of the aorta may save life. Momburg's bags are best for this purpose. A. Mayer of Tübingen stated that the use of Momburg's bag is serious in cases of a diseased cardiovascular system. If the bag works imperfectly even in healthy cases a deadly hemorrhage into the veins may occur. O. Küstner of Breslau believes that the extraperitoneal cesarean

section is preferable to all others. It may be safely applied in infected cases. It offers better facilities for extraction of the child. Baumm of Breslau said that the extraperitoneal cesarean section cannot always be carried out. The peritoneum is ruptured in about one-third of the cases. But this operation is also about three times as safe for the preservation of life. It can be applied more safely also in infected cases, and insures greater safety to the child.

Among the miscellaneous contributions presented on the third day, of which there were fifty-three, read in abstract, the following may be mentioned: Heinrich Lopez of Valencia discussed "Uterine Prolapse." He attributed the embarrassment experienced by all gynecologists in selecting a method of operation to a lack of understanding the cardinal principles involved in the dynamics of the female pelvis. Landau's procedure deserves the preference because this surgeon extirpates the uterus, which is always useless and generally diseased. The operation is characterized by an incomplete hysterectomy, preserving only the isthmus, viz., the insertion of the sacrouterine ligaments. The muscular piece thus preserved serves as a center of resistance in the extraperitoneal cicatrix block. Landau's perineoplasty assures pelvic support.

J. Riddle Goffe of New York said that in dealing with cases of prolapsus uteri with attendant rectocele and cystocele, the important factor to be reckoned with is intraabdominal pressure. Neither the floor of the pelvis nor any conjunction of tissue can resist the direct action of this force by means of its textural resistance. Nature has supplied a system of deflecting planes, therefore, to receive, direct, and divert it. The deflecting plane that first receives the impact is the uterus with its broad ligaments. This must be preserved or an efficient substitute should be supplied if permanent results are to be secured. These are to be attained by shortening the uterine ligaments or, in extreme cases, by removing the uterus and substituting the plane of broad ligaments, preserving intact all the uterine ligaments and attaching them to it. The details of the operation were explained and results were given.

Arthur Stein of New York presented the present status in America of the operation for carcinoma uteri. The records at present are sadly incomplete, but the American contingent, with the increasing number of cases, are awakening to the demand upon them for greater care in the study of cases and their remote results. It is rather premature to attempt to draw reliable conclusions or give a complete picture of the situation. Still, as far as they went, the results were encouraging to the operators who were giving special attention to the disease.

Comparison of Simultaneous Polygraph and Micrograph Tracings.—F. S. Meara, T. H. Coffen and A. C. Crehore from a study of a number of tracings conclude that the delicate mechanism of the micrograph registers the movements in the heart and blood-vessels more accurately than does the polygraph. The inertia of the polygraph lever and diaphragm distorts the tracing. The difference between the results obtained with the two instruments is shown by the records made simultaneously with the micrograph and the polygraph. The micrograph is particularly useful for recording heart sounds. While the micrograph will not supersede the polygraph or electrocardiograph, the authors feel that it has distinct possibilities as a clinical instrument.—*Journal of Experimental Medicine.*

THE FIFTEENTH INTERNATIONAL CONGRESS ON HYGIENE AND DEMOGRAPHY.

(Special Report to the MEDICAL RECORD.)

VITAL STATISTICS IN THE UNITED STATES—BIRTH REGISTRATION—CLASSIFICATION OF CAUSES OF DEATH—THE TRAINING OF DEMOGRAPHERS—PARATYPHOID BACILLI—MARKET MILK—SCHOOL INSPECTION—MANAGEMENT OF TUBERCULOSIS IN SCHOOL CHILDREN—SOCIAL ASPECTS OF PHYSICAL DEBILITY AND MENTAL EFFICIENCY—IMMIGRANTS IN PUBLIC SCHOOLS—FOLLOW-UP SYSTEM IN SCHOOL INSPECTION—BACTERIA CARRIERS.

WASHINGTON, D. C., September 25, 1912.

IN the Section on Demography under the presidency of Prof. Walter F. Willcox, president of the American Statistical Association, Cornell University, Ithaca, N. Y., the first paper on the "Development of Vital Statistics in the United States Since 1900, and Measures Needed for the Immediate Future" was read by Dr. Cressy L. Wilbur, chief statistician for vital statistics, U. S. Census Bureau, Washington, D. C. He thought that the extension of the registration area during the past decade was largely due to the adoption of the "model law." The county systems had failed. American methods are best adapted to conditions in the United States and will ultimately yield fully satisfactory results. He said that the measures needed for the immediate future were active work for the extension of vital statistics throughout the South, more thorough enforcement of registration laws, especially the provisions for the registration of births; education of the American people in regard to the personal, legal, sanitary, and social importance of such laws, and greater utilization of the vital statistics now available; elimination of discrepant and worthless "statistics"; aid from the Children's Bureau, the American Association for the Study and Prevention of Infant Mortality, and the proposed Public Health Bureau; active co-operation by Congress with the States for the promotion of vital statistics.

Then followed the reading of several papers showing the work that was being done in certain States in the collection of statistics, among them one by Dr. Eugene H. Porter of New York on the Improvement in Birth Registration in his State. He said that at the present time only about 6 per cent. of the births occurring in New York State escaped registration, whereas in 1900 it was estimated that over 20 per cent. were not reported. It is hard to estimate the true birth-rate of any large municipality or State, but it is safe to say that the registration of deaths in the State of New York is practically complete, and that the registration of births is within 10 per cent. of being complete.

Dr. Peter H. Bryce, chief medical officer to the Bureau of Emigration, Department of the Interior, Ottawa, Canada, read a paper on the "Relation of Rural and Urban Populations as Shown by the Census in the United States and Canada to Public Health Problems." The figures he presented made it abundantly apparent that in Canada, even more than in the United States, in spite of every effort to place immigrants on the land, the total outcome of immigration had not equaled in rural increase the natural increase of the population of Canada in 1901 at a rate of increase of 12 per cent. in ten years. While the total population of Canada had increased 34 per cent. the total urban increase was 62.25 per cent. Some of his figures illustrated the relationship between slum population and insanity.

Dealing with prevention, Dr. Mott said: "If it can be shown that there is a correlation between insanity, tuberculosis, alcoholism, syphilis and overcrowding, in one-room premises, and insanitary dwellings in our large cities, it might be asked whether public money would not be better expended in solving the housing problem than in spending vast sums on sanatoriums and lunatic asylums in the hope of dealing with mental and physical degeneracy."

Dr. Jacques Bertillon read a paper on "Classification of the Causes of Death, Modifications Adopted in 1909, and Those Which May Be Necessary in the Future," in which he recalled the history of the question and said that this history should enlighten us as to the future.

Statistics require uniformity in figures which are intended to be comparable in different countries and at different periods. It has need, then, of lasting classifications. It cannot possess a lasting classification of the causes of death, if that classification is based upon the anatomical seat of diseases. In 1891 the International Institute of Statistics commissioned M. Jacques Bertillon to draw up one. M. Bertillon founded his classification upon the anatomical seat of diseases, endeavoring throughout to make his headings comparable to those of the chief nomenclatures then in use.

The American Public Health Association, having recognized the necessity for a uniform classification, has agreed to recommend that of M. Bertillon. But that the advances of science might not, in the future, find this classification to be antiquated and inacceptable, this association suggested that it be revised every ten years; the first revision to take place in 1900. This was done; and the second revision occurred in 1909. This nomenclature is to-day adopted by all the States of North and South America; by all the extra-European countries which compile statistics (notably by the British colonies and by Japan). Even in Europe it has been accepted by the entire western part of Europe (Great Britain, France, Spain, Belgium, Holland), and by several other countries (Austrian cities, Bulgaria, Roumania, Russian cities, and so forth). The tendency of a great many physicians is to revert in part to an etiological classification, because this appears to them more scientific. But a statistical classification is not designed to present a summary of general pathology; its aim is humbler, but more practical; it is to sum up as exactly as possible the thousands of always brief, and often incomplete, answers which physicians inscribe upon official death-reports. That is alone the object to be pursued. Beyond that, the statistical tables which present this summary should have as durable a form as possible. For these two reasons, the anatomical classification must be adopted.

In the afternoon the Training of Demographers was discussed. Dr. Eugene Würzburger, Director of the Royal Statistical Office of Saxony, Dresden, told how the great increase in the number of statistical offices and officers of recent years had led to such training being given at a number of the universities and other advanced schools by statistical lecturers and seminars, given regularly or at current intervals. A questionaire regarding the kind and object of such an education in higher institutions was now being organized by the German Statistical Society. It extended to other higher institutions lying outside the German Empire, in Austria and Switzerland. M. Lucien March, Director of the General Statistics of France, Paris, told how statisticians were secured in France, and Professor Walter Wilcox of Cornell University spoke of the demand for and the supply of them in the United States.

In the Section on Hygiene, Microbiology, and Parasitology the subject of paratyphoid-like bacilli, with special reference to their dissemination in nature and their relation to man and animals occupied the morning. Regierungsrat Prof. Dr. A. Weber read the first paper. Dr. Sacquepée, Paris, France, discussed the paratyphoid bacilli in their relation to animal foods. The animal foods most frequently affected are meats and milk. Infection of the meat may be present because the animal was infected by a disease caused by paratyphoid bacilli and may be unaccompanied by any appreciable lesions. In all cases it is septicemia which causes the most important phenomena. A meat primarily healthy may be infected after slaughtering. Man may contract infection either by direct contact or by ingestion. The prophylaxis to be aimed at is the isolation and disinfection of the infected person, the sanitary inspection of all persons having anything to do with the alimentary profession, the inspection of animals after slaughtering, the inspection of pork meat shops, and the education of the public as to the use of infected foods the possible danger from raw meats. Dr. John C. Torrey of New York considered the representatives of the Gärtner group isolated from the tissues of laboratory animals. He said an investigation into the etiology of canine distemper had disclosed the fact that the *B. enteritidis* was not infrequently present in the organs of dogs suffering from this disease. In a series of 90 distemper cases the bacillus was isolated from the tissues of 13 dogs, it having been found in one or more of the following localities, blood, lungs, liver, spleen, trachea, or nose. Bacilli, which were probably identical with the *B. enteritidis*, have been reported by a few others as occurring in dogs, but they have not been identified beyond placing them in the paratyphoid group. It would seem, then, that the importance of the dog as a source and locus of multiplication of the meat poisoning bacillus has not been recognized heretofore. The author's studies indicate that dogs dying from distemper may eliminate vast numbers of these dangerous organisms, and may be a source of infection for meat-producing domestic stock.

Dr. P. G. Heinman of Chicago read a paper on the "Examination of Market Milk" in which he said that the investigation of market milk made during the past months had for its aim the attempt to discover more precise methods of routine examinations of milk. The results do not warrant recommending a departure from methods practised at present in board of health laboratories. A few significant facts, however, are brought out by the investigation.

Examination of 215 samples of milk bought in the open market in original packages showed that pasteurized milk, as sold in Chicago to-day, is cleaner than raw milk. It contains less than one-fourth the number of bacteria contained in raw milk. This number would be much smaller, if pasteurization were universally of high efficiency. Methods of commercial pasteurization of milk are still in a stage of evolution, but development has progressed to a degree which will insure efficient pasteurization within a few years. The fact was also brought out that pasteurized milk turns sour the same as raw milk, the process being somewhat delayed. The

study showed that only the total number of bacteria can serve as an index of dirt in milk.

In the Section on Hygiene of Infancy and Childhood, "School Inspection" was the subject under discussion on Tuesday afternoon and Wednesday morning. Dr. Josephine Baker of New York considered the causes of malnutrition in school children, making reference to those caused by conditions in the home and those caused by conditions in the school. Dr. Walther Ewald, Frankfürt à M., Germany, spoke of the "Campaign against Infectious Diseases of Children." He said that all contagious diseases have either yielded to modern hygiene and the fight against epidemics or have at least been greatly affected by them, excepting infectious diseases of children, which in part only are true children's diseases. All cause great ravages among the children, so that far more die of these diseases than of all other infectious diseases combined; in comparison with these, the total number of victims of cholera and typhoid fever is far less. This condition prevails throughout Europe. The terrible effect of contagious diseases of children is disclosed not merely by mortality statistics, but by a general decline of young people. The battle cannot be the same as in other infectious diseases where we have to proceed against bacterial components. Exciting and disseminating agents are rarely found in children's diseases. In order to combat the diseases themselves special measures are necessary. The systematic campaign carried on in accordance with the usual means for combating epidemics has proved inefficient in Germany, and particularly in Prussia; no effort is made to combat measles and whooping-cough. In reference to the "Management of Tuberculosis Among School Children," Dr. Arthur T. Cabot of Boston said that in caring for feeble, anemic, undernourished children, those who might later develop tuberculosis, open-air rooms or indeed out of doors, with short hours of work and extra feeding, had given such excellent results that the open-air treatment of ailing children was now widely accepted and was being more and more widely adopted. Upon the whole, the hospital school was the best means yet devised for caring for the already tuberculous child. This afforded less isolation than a hospital and a nurse followed the child home and instructed the parents in preventive measures.

Dr. Isabelle Thompson Smart of New York read a paper on the "Relation of Physical Debility and Mental Deficiency to the Body Social," in which she presented facts showing that our pressing needs are: Greater latitude in the arrangement of the school curriculum; greater scope in, and application of, school hygiene; the need of an increased and more comprehensive propaganda in the instruction of mothers and fathers in the hygiene of daily life; the absolute necessity of more school clinics and more hospital clinics arranged at hours to suit the needs of the school child, instead of as at the present, during the hours of the school day; the urgent need of after-care committees to guard and protect —in so far as possible—the children who suffer in any degree from mental defect; the necessity for legislation to meet the present needs in the proper care of mental defectives and to prevent any reproduction of their kind; and the urgent necessity of the building of more colonies—in all our States—for the permanent care of aments. "The Relation of Teacher and Pupil, with Special Reference to the Education of Immigrants in American Public Schools" was the phase of the subject considered by Dr. William E. Chancellor of Norwalk, Conn. Observation at close range of boys and girls of forty-two races and nations through a period of four years, with a detailed study of 1,500 out of 4,000 in all seemed to indicate the following conclusions: (1) Brachycephaly, mesocephaly, and dolichocephaly in its two forms—Mediterranean and Teutonic—each has its definite temperamental meaning. (2) Certain races are precocious, others are normal or average and still others are altricious —each of these conditions makes a temperamental condition as its phase or result. (3) The food supply in each generation makes a difference to the hereditary temperament. Food supply must be considered with reference to quantity, quality, preparation, and time and condition of serving. (4) Certain other factors enter in but not in a large way. These are easily specified. (5) Sex concerns temperament vitally. (6) All the foregoing is to be applied both in the case of the pupils and of the teachers. Dr. Helen MacMurchy of Toronto, Canada, expressed the opinion that medical inspection of schools widens the teacher's horizon and brings the school room into the sphere of interest of modern preventive medicine. The average school child may be made a sanitary reformer and the teacher is the only one who can do it; the physician should tell her how. She spoke of the factors that militated against the health of the teacher and believed that medical inspection removed these. If we were to get the best results from medical inspection the teacher must be made to see that she would profit as well as the pupils. Dr. Thomas A. Storey told of the results of a "Follow-up" system in medical inspection. He said that in the department under the author's supervision an attempt had been made to secure a method of instruction in hygiene which will develop permanent health habits in the individuals that came under its educational influence. One phase of the work included medical inspection. He preferred to call it individual instruction in personal hygiene. Medical inspection became a part of the method of securing information concerning the hygienic needs of the individual, and a basis on which the individual must be given advice bearing upon his personal health problems.

The percentage of parents that refused to secure treatment for their children during the year ending June 1, 1911, was seven-tenths of 1 per cent., and for the year ending June, 1912, eight-tenths of 1 per cent, thus showing this method of medical inspection to be effective. It was securing the repair of physical defects and correcting unhygienic conditions in over 90 per cent. of cases under observation. It was improving the physiological efficiency of at least a thousand boys every half year. Professor Gustav Alexander of the University of Vienna entered a plea for the examination of the ears of school children.

In the Section for the Control of Infectious Diseases the morning session was devoted to the discussion of bacteria carriers, especially as to their influence in the dissemination of infection and as to the attitude which sanitary authorities should adopt toward them. Dr. J. C. C. Ledingham, Lister Institute, London, England, read an exhaustive paper on the subject in which he said that bacteriological researches during recent epidemics of enteric fever, of diphtheria, of cerebrospinal meningitis, and of cholera had shown that the clinical manifestation of an infection might vary widely from the classical text-book description, in fact it might be so mild

that it could only be detected by serological analysis. He discussed the practicability of examining all convalescents from typhoid fever before they left the hospital and of a continued surveillance of those who still carried the bacilli when they left. As to the treatment of carriers he said that none of the methods tried had proved entirely satisfactory and that there was need of further experimental work on animals with the object not only of discovering some effective means of sterilizing chronic carriers but also of finding some more rational method of treating those actually sick with the infection that would prevent their becoming carriers. He thought there was need of legislation which would enlarge the powers of health officials so as to give them power to prevent recognized carriers from engaging in employments which called for handling of milk or other foodstuffs. There should be some system of instructing chronic carriers as to the necessity of careful hygienic habits. As to the diphtheria carriers something could at times be accomplished by local treatment and in certain cases removal of the tonsils after giving an immunizing dose of antitoxin. He also brought up the question as to the virulence or non-virulence of the carrier. As to cholera carriers, he said that one-half of those cured of the infection continued to be sources of danger for from ten to fourteen days, while five or six in every hundred remained infectious for more than twenty-five days. Of the latter one or two might continue to be carriers for two or three months. There were many difficulties in ship inspection and the bacteriological examination of excrements of passengers. Attention might also be called to the fact that there might be in certain cases intermissions in the excretion of specific germs. Dr. Charles Norris of New York said that at Bellevue Hospital they gave instruction as to hygiene to convalescent carriers when they left the hospital and then the Board of Health followed them up. In the routine examination of a series of 132 cases a year ago they found that 93 per cent. of the convalescents were free from the bacilli two weeks after they recovered. He thought that perhaps the ideal way to deal with chronic carriers would be to separate them in institutions. All who had had typhoid at any time might be regarded as suspects and all carriers should be excluded from occupations calling for the handling of food. This section spent the remainder of the morning in discussing the importance of flies and other insects as carriers of disease, Dr. Mesnil of the Pasteur Institute, Paris, France; Dr. L. O. Howard, Chief of the U. S. Bureau of Entomology, Washington, D. C.; Professor George H. F. Nuttall of Cambridge University, England; and Dr. Samuel T. Darling of the Board of Health of Ancon, C. Z., taking part.

1. **The Filterable Viruses.**—S. B. Wolbach states that one group of diseases caused by a filterable virus require entrance of the virus directly into the tissue through an abrasion or injury to the surface of the body. These are rabies, molluscum contagiosum, verruca vulgaris, chicken sarcoma, and probably trachoma, though it is possible that the last may effect a hold on a normal conjunctiva. Another group are transmitted by contact, which, of course, means contamination with infected material, such as discharges from the eyes, respiratory tract, surface lesions and excreta. These are: pleuropneumonia of cattle, cattle plague, distemper of dogs, fowl pest, fowl diphtheria, infectious stomatitis papulosa of cattle, and the infectious agalactia of sheep and goats. Contagious or possible "airborne" diseases with filterable viruses are sheep-pox, hog-cholera, measles, foot and mouth disease, variola and scarlet fever. The methods of transmission of guinea-pig epizoötic, guinea-pig paralysis, and Novy's rat disease are unknown. A number of these diseases, under which are included the most contagious, as foot and mouth disease, variola, sheep-pox, hog-cholera, measles, and scarlet fever, and others less easily communicated, such as rabies, trachoma, molluscum contagiosum, distemper of dogs, fowl pest and epithelioma contagiosum of fowl, have associated in the lesions cell inclusions which are more or less specific for the particular disease. Von Prowazek has given particular attention to these cell inclusions and has created for them the name "Chlamydozoa" in the belief that these inclusions are parasitic, a view held by comparatively few pathologists and bacteriologists.

3. **Surgical Importance of Acapnia.**—F. J. Cotton notes that hysterical hyperpnea may produce general acapnia of serious grade and that Henderson's observations on the loss of peristalsis from local acapnia, and on the restoration of peristalsis by remedying the acapnia, are directly applicable to man as well as to the laboratory animal. Acapnia of the general type is readily remedied if treated promptly by the surgeon. Local acapnia in laparotomies is easily handled, with little apparatus, without danger of infection, and not only without loss of time, but with a time-gain due to the easy handling of intestines which are in a normal, rather than in a distended or acapnic condition.

2. **Intestinal Putrefaction.**—C. C. Sutter points out that the important factors favoring the production of intestinal putrefaction are as follows: (1) Impaired metabolic processes and errors in diet. On a protcid diet the stools are neutral or alkaline, and contain ammonia, fatty volatile acids, ptomaines and leucomaines, aromatic oxyacids, phenol, and indoxyls, etc. On a carbohydrate diet these substances are greatly reduced in amount or are entirely absent. (2) Numbers of bacteria are taken into the digestive tract with the food, and from nose and throat disturbances. (3) Obstinate constipation. (4) Delayed absorption. (5) Insufficient mastication, improperly cooked food, food partially decomposed, or food containing preservatives. (6) The number, character, and activity of the saprophytic bacteria. These are increased in number and virulency by stasis of the fecal content and by alterations in the bile, gastric, and pancreatic juices which have an inhibitory influence. (7) Reactions of the contents of the intestines. Anaërobic albuminous putrefaction cannot take place in the small intestines and is very limited in the large intestine when the contents are normally acid. (8) Disturbances of the abdominal organs, such as gastroptosis with or without coloptosis, kinking, redundant or ptosed colon or sigmoid, chronic appendicitis, and par-

tial or complete occlusion of the common bile duct, with or without jaundice.

5. **Malarial Hemoglobinuria.**—A. Woldert has observed that in blackwater fever there is a reduction in the normal percentage of polymorphonuclear leucocytes, occurring within a few hours of the time of onset of the paroxysm of hemoglobinuria and persisting for several days subsequently. In all the cases of the author's series the large lymphocytes seemed to be increased from the time of onset of the paroxysm of hemoglobinuria to several days subsequently. It seems probable that this increase in the number of large lymphocytes indicates the malarial origin of the condition. During the course of malarial fever (especially a chronic case in which quinine has been given) there appear to be two different agencies operating, either one of which has the power of producing hemoglobinuria; these two agencies are the malarial parasite and quinine.

6. **Treatment of Acute Staphyloma of the Cornea.**—P. J. Pontius states that the adrenal active principle has no specific effect upon the corneal tissue, but it reduces staphyloma of the cornea by constricting the arterioles, thus relieving the pressure in the lymph areas, and in this manner causing the reduction of the intraocular tension and permitting the cornea to resume its normal form.

1. **Cardiac Complications of Pregnancy.**—F. S. Newell states that while the strain of pregnancy is generally well borne by the normal heart, any organic lesion in this condition calls for constant watchfulness on the part of the medical attendant, even though it may be perfectly compensated under ordinary conditions. Pregnancy occurring in such a case, with imperfect compensation, calls for immediate emptying of the uterus, since the already disabled heart has no chance of sustaining the added burden. When failure of compensation occurs during pregnancy attempt should be made to restore it by rest and appropriate treatment, and if this does not succeed the pregnancy must be ended and future pregnancies be forbidden. In cases with demonstrated heart lesions, even if they have given no trouble during pregnancy, labor should be regarded with apprehension and every effort made to shorten it. A patient with a compensated organic disease usually stands operation well, but operation after failure of compensation will often be disastrous. A patient with organic heart disease and contemplating marriage should be warned as to the risks of pregnancy and labor, the prognosis in each case depending on the nature of the lesions, the age of the patient, and her previous history as regards the behavior of the heart under normal conditions. It is impossible to estimate accurately the efficiency of the heart-muscle after failure of compensation, since, although it may have been restored under treatment, death may occur suddenly before, during, or after labor. Labor should be shortened as quickly as possible whenever demonstrated organic lesions exist, although they have caused no unfavorable symptoms. In primiparæ the propriety of cesarean section, which may relieve the strain on the heart, may well be considered, especially with rigidity of the soft parts. Mitral stenosis calls for most careful observation. Any sign of failing compensation should be met promptly and if anything occurs accompanied by a rise in arterial tension the pregnancy should be terminated at once.

9. **The X-Ray Treatment of Leucemia and Pseudoleucemia.**—By A. Stengel and H. K. Pancoast. (See MEDICAL RECORD, Vol. 81, page 1115.)

16. **The Complications of Tabes.**—E. L. Hunt discusses these complications and their treatment. The most extensive and all-embracing group of complications includes crises and the one most frequent of all is the pain crisis, for which the author advocates local measures and the simpler drugs, such as aspirin, pyramidon, salipyrin and codein. In the gastric type the most serviceable drugs are cerium oxalate in 5-grain doses every half hour, minute doses of strychnine, antipyrin and bicarbonate of sodium. The importance of urinary complications, which occur in about 90 per cent. of cases, has been underestimated. Among the unusual complications are the fractures and joint troubles. Perversions of the sympathetic function have been noted. The tabetic is especially liable to coldness of the extremities and capillary stasis. Delirium simulating alcoholism, and almost every variety of mental disorder may appear. A rarely mentioned but by no means unusual complication is morphinism. Hemoplagia, temporary or permanent, is not uncommon. A rare complication is that of progressive muscular atrophy..

11. A Review of the Congress of Alienists and Neurologists of French-Speaking Countries, 1912. R. Jones.

2. **Vertebral Ankylosis.**—J. Dardel discusses the following types of this condition: rhizomelic spondylosis, Bechterew's heredotraumatic kyphosis, osteophytic vertebral rheumatism, and deforming spondylitis.

3. **Pancreatic Diabetes.**—F. P. Knowlton and E. H. Starling report the results of their experiments which seem to indicate that the pancreas normally produces a hormone which circulates in the blood, and the presence of which is necessary in order that the tissue cells may be able to assimilate and utilize the sugar of the blood.

6. **Movable Kidney and Chronic Colitis.**—J. Liddell states that the frequent association of movable kidney and chronic colitis has been recognized by various observers, and most of them consider there is a causal relationship between the conditions. There is, however, a diversity of opinion as to the nature of this relationship. Debove and other observers hold the view that the ne-

phroptosis is not only a cause of enterocolitis, but is the most frequent cause. Others, again, hold the opposite view, and consider that nephroptosis is due to colitis. The frequency with which movable kidney occurs in cases of colitis is remarkable. Both kidneys may be movable, but that is not often the case; more generally it is one kidney, and in a large percentage it is the right one. The author has seldom seen a patient with nephroptosis who is not also affected with colitis, even in those in whom the loose kidney was attributed to an accident. The exceptions have been chiefly in cases of visceroptosis where the kidneys have become displaced along with the other viscera. Nephroptosis is a fairly common condition, and like enterocolitis it is much more common than many of the profession have yet realized. It is a troublesome complication in colitis, especially when the kidney is freely movable and floats about the abdomen or becomes fixed by adhesions.

8. Intravenous Injection of Paraldehyde.—H. L. C. Noel and H. S. Soutar find that the intravenous use of paralydehyde is practicaly safe as a hypnotic in cases of grave cardiac and pulmonary disease. They do not suggest that it can replace the slower but more lasting hypnotics, but draw attention to it as a method by which under the most trying circumstances they have never failed to induce within 60 seconds a condition closely resembling normal sleep.

6. The Contagiousness of Leprosy. J. W. Lindsay.
7. Strangulated Inguinal Hernia in an Infant. G. E. E. Nicholls.

2. The Chief Use of the Peritoneum.—J. Howell amplifies his theory of the use of the peritoneum. In addition to its well-known uses as a mechanical lubricator for the efficient movement of the intestines, as a lymph sac, as a secretory and absorptive gland, its greatest use is that of a perienteric trap for the reception and annihilation of microorganisms which constantly and normally—that is, without producing symptoms—permeate the intestinal wall. It is part of the duty of certain organs intimately connected with the peritoneal cavity, of which the liver, stomach, and intestines are the chief, to excrete the toxic products formed therein, including, in times of stress, the bacteria themselves, with the minimum risk of contamination to the remainder and more important parts of the body.

4. The Subjective Method for Estimating Blood Pressure.—H. G. Armstrong refers to the auditory method for estimating blood pressure. This was first introduced by Korotkow of St. Petersburg in 1905, and made known in England by Oliver five years later. Instead of using the finger on the radial pulse, a stethoscope is applied to the brachial artery at the bend of the elbow; on the return of the blood beneath the armlet a distinct throb becomes audible, which gradually increases as the pressure lessens, and then gradually dies away and disappears on the complete relaxation of the constricting band. The auditory method gives not only the high point—the systolic pressure very definitely—but it also gives the low point; under normal conditions the point of maximum throb is midway between these points, and this is generally accepted to be the indication of diastolic pressure. Since the author's attention was called to the auscultatory method, he has always employed it, finding it more accurate and comprehensive than the digital. He found, however, in taking his own pressure that he was able, with equal accuracy, to estimate by his own sensations the moment when blood commences to return beneath the armlet, and that at which, the pressure being entirely relaxed, there is no obstruction to the circulation. The throb which is audible through the stethoscope to the ear of the observer, is equally felt by the observed. With a little education the point of maximum throb can be determined. This method is called by the authors the subjective method.

Berliner klinische Wochenschrift.

September 9, 1912.

Severe Gestation Toxicoses.—Freund reports four cases of severe toxicosis at the close of gestation, the latter having been uneventful throughout. Two patients had manifest eclampsia, the cases ending fatally. In a third fatal case the cause of death is given as latent eclampsia. The fourth patient recovered and had no cerebral symptoms at any time. Not only this patient, but two of the others presented the picture of severe hematogenous icterus. In all the fatal cases there was acute hemorrhagic diathesis. The infant in the recovered case was born with evidences of a toxicosis, notably prolonged somnolence, but eventually rallied. The author is an adherent of the unicistic view, which assigns the morbidity of pregnancy to one single cause or cause nexeis. Attempts to estimate the severity of the toxicosis *intra vitam* by urinary studies are unsatisfactory. Autopsies alone throw light on these cases, and even then, owing to the great number of finds, the evolution of the malady cannot be fully traced. A diagnosis of latent eclampsia is hardly justifiable without autopsy. If we then find all the lesions of manifest eclampsia present the diagnosis is warranted. Authors have erred at times, says Freund, in representing severe toxicoses as something apart from eclampsia, when the latter was merely latent clinically. The writer has nothing to say of those fatal toxicoses which occur early in pregnancy, in which a diagnosis of latent eclampsia would be absurd. On the other hand, all toxicoses at term would necessarily be regarded on all sides as eclamptic in character.

Influences of Fetal Death on Pregnancy Nephritis.—Molinari sums up a case as follows: A secundipara in the seventh month of gestation with high degree pregnancy nephritis was admitted by the clinic with an eclamptic aura. The convulsions remained in abeyance, and on the seventh day, the fetus having been pronounced dead, the nephritis showed sudden improvement. The dead and macerated fetus was later expelled. It is, of course, possible that the sudden involution of the nephritis was a coincidence, but as the case stands the inference is warranted that the mother was being poisoned by some fetal metabolite, and that when the manufacture of the latter terminated with fetal death the mother promptly improved. There is no mention of parallel cases, although this case was treated in Prof. Bumm's Berlin clinic.

Menstrual Fistula.—Hirschberg reports two cases of this condition as follows: A woman, aged 23, who had borne children twice, was operated on for probable cystoma, the details being unknown. An abdominal fistula persisted, which discharged blood at each menstrual period. The fistulous tract was eight cm. long and was covered with bad granulations. The latter were curetted, the fistula drained with gauze and healing resulted. The other case was similar in character, the fistula having resulted from an operation for pus tube. Closure by simple measures has thus far failed. It is evident that in these cases the menstrual blood did not come from the uterine mucosa, and the inference at first would be that it was of tubal origin. The subject of tubal menstruation is not yet a closed chapter, and we do not know to what extent it is physiological. Any other supposition would require that this fistula blood represented a vicarious menstruation.

The author believes from the incomplete evidence that the blood reached the fistula from an opening in the tube.

Münchener medizinische Wochenschrift.

September 12, 1912.

Intraperitoneal Application of Camphor Oil.—Hirschol first mentions the current interest shown by gynecologists on this subject. Through multifold administration, improvements, etc., excrescences have developed upon the original idea which threatens to lead to its abolition. The author is convinced personally from his own experience of the excellence of this resource. In 1907 he recommended the 1 per cent. camphor oil in actual peritonitis upon the theory that the oil sealed up the lymphatic openings and thereby prevented the absorption of toxins. He is not shaken in his convictions by the adverse criticism. The peritoneal cavity is mopped clean of pus with gauze strips, the oil applied throughout and the abdomen closed down to the drainage tube. The amount of oil used may reach 200 or 300 c.m., but quite a percentage of this escapes before the abdomen is closed. The actual quantity of camphor in the oil is about 2.5 grams at the most. The camphor acts as an analeptic, and it is no longer necessary to inject it subcutaneously after operating. Nothing could be gained by increasing the amount of camphor. Hoehne and others, however, have used as high as 10 per cent. camphor oil in the belief that a reactive peritonitis is set up with destruction of bacteria. No toxic consequences have been noted, but delicate subjects have exhibited pallor, sweating, and even fainting. For this reason a return to weak concentrations has been urged, and none too soon, for very recently a death has been attributed to the 10 per cent. oil. The ability on the part of the oil of preventing adhesions has not been insisted on, but that it sometimes has this effect seems certain. Since these cases of peritonitis may end fatally autopsy evidences are forthcoming, and the author has thus been able to convince himself that the oil may prevent the adhesions. The fallacy of assuming that oil or any other influence can prevent adhesions is apparent in the fact that the latter do not always form if the case is left to itself. Quite recently Novak has sought through results of animal experiment to show that the oil prevents adhesions, but the opposite conclusion was forced upon him. Novak sought to eliminate the peritoneum by leaving the cavity denuded to a considerable extent, but adhesions still developed.

Epidemic Appendicitis.—Martin describes some experiences on a cadet school ship of the North German Lloyds Co. This was a sailing vessel which was making an extensive world journey. The first victim was a senior year cadet who developed a typical case, having already had one previous attack. Ten days later a classmate suffered from the same trouble, and not long afterward the third officer of the vessel was attacked. About five or six months later the fourth victim, a senior, was stricken, while patient number three had a recurring attack. Next a junior furnished still another case. There were in all six attacks on five subjects. The author was not prepared for operation and had to temphorize until suitable ports were made. There appear to have been no factors present which could have determined this cumulative incidence.

Deutsche medizinische Wochenschrift.

September 12, 1912.

Treatment of Insomnia.—Meyer gave a clinical lecture on insomnia in a neuropathic child, the result of measles. Insomnia, if actually what the name implies, suggests an oncoming psychosis. As a rule the condition called insomnia means really only diminished sleep. We may see insomnia of brief duration as a result of due causes. First we have to determine the limits of normal sleep. We see an evening type and a morning type under normal circumstances. The former is affected chiefly in childhood and the latter in adult life. Disturbed sleep without some causal factors in plain evidence is not common. A periodical visitation of diminished sleep is so common as to suggest a cyclical psychial disturbance, and this element may be found to be present in the absence of other efficient causes. The inability of neuropathic children to fall asleep may usually be traced to some exciting event which transpired during the previous day. In other cases insomnia may be traced to hallucinations or illusions upon falling asleep or dreams occurring after sleeping. For a somatic cause the presence of round worms suggests itself. Adults are much more subjected to peripheral factors which interfere with sleep, for these so often depend upon organic degenerative changes. So, too, the child insomnia is seldom traceable to tea, coffee, tobacco, alcohol, opium, etc. Insomnia is an important symptom of hysteria and neurasthenia. The general management of insomnia embraces in the first place hydrotherapeutic procedures or drugs. The first to be thought of are the antispasmodics, which means today the various preparations of valerian in the first place, while next in order and at some distance come drugs like asperin and pyramidon. Remedies which quiet petulant restlessness are superior to those which act directly upon the nervous centers, and the author regards the bromides as belonging to the former rather than the latter class. Some use may be made of all these drugs, while actual hypnotics are to be avoided save in absolute insomnia. When their use seems imperative two or more may be given in combination, which, according to Bürgi, can be taken advantage of in the interest of economy of dosage by giving one drug in the usual dose while the other is prescribed in a fractional dose. Alternation of a number of drugs is also a good plan to prevent cumulation and addiction.

Use of Hypophysis Extract in Weak Labor Pains.—Fries sums up the experience of the Greifswald obstetrical clinic with this oxytocic and also with its competitors as follows: The preparations of the hypophysis are dependable and safe, and indicated in the periods of dilatation and expulsion when there is no obstruction and no indication to terminate labor by operation. In the third stage it is not so dependable and ergot does much better. In missed labor and when premature delivery is indicated hypothysis preparations are not sufficient to induce labor alone, but may cooperate with other measures. In regard to the excitation of normal labor at term this is increasingly apparent the nearer the time of administration approaches that at which spontaneous delivery would set in. That the drug really brings about labor without actual assistance from nature seems evident from the fact that hypophysis labors seem considerably longer than normal ones; or, in other words, hypophysis preparations delay normal labor when given without indication. As already stated hypophysis extract is nontoxic and will combine readily with all other drugs given during labor. Unlike some authorities, the writer believes that the extract should be used by the family practitioner as greatly preferable to the "forceps for convenience." The author does not find that the extract lightens postoperative bladder troubles.

Fibrocaseous Tuberculosis of Glands in Neck; Caries of Dorsal Spine.—R. Hutchison reports the case of a man, aged 46, who twenty-four years ago had a large swelling in the neck which persisted for some months and then entirely disappeared. About a year ago he underwent an operation for fistula and shortly afterwards the swellings returned and have persisted since, although they vary greatly in size from time to time. He had never been aware of anything wrong with his back. Masses of enlarged fibrocaseous glands in neck. No enlarged glands elsewhere. Skiagram shows caries of two dorsal vertebræ. —*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE URINE.

Résumé of the Steps in a Chemical Uranalysis.—Note whether clear or turbid; if the latter, find out to what it is due.

Take the specific gravity. If above or below the limits prescribed by the company interested, get another specimen and subject it to a complete chemical analysis.

Test the reaction with both blue and red litmus paper to determine whether it is acid or alkaline.

Test for albumin by the heat test. If this gives absolutely no reaction, the examiner may safely say that the urine contains no albumin. If it gives any reaction at all, test the urine then by Heller's test, letting it wait at least fifteen minutes if necessary. The use of the heat test is advised at first, for it requires only a few minutes and a negative reaction with it is conclusive. The examiner should state distinctly in his report to the company what he finds with each test if they give different reactions, even if he thinks that the reaction is due only to necleoproteid.

Test for sugar by one of the reduction tests, Fehling's, Haines', or Nylander's. If no reaction is obtained, it is certain that the urine contains no sugar of clinical importance. If a reaction is obtained with one of these tests, it should be corroborated by fermentation, as a positive reaction with the latter is conclusive. If, however, a negative reaction occurs with fermentation and a positive reaction with a reduction-test, the examiner should state the full findings in his report to the company.

Microscopical Examination of the Urine.—The clinical significance of red blood cells, leucocytes, and renal casts depends largely upon the number of these bodies, whether they persist or not in being present, and the cause; also the age, personal history, and condition of the applicant. A few red blood cells or leucocytes will often be overlooked if they are not indicative of some serious or chronic trouble. Considerable judgment is required in determining the value of renal casts as a sign of present or impending disease.

Mucous cylindroids must be distinguished from true casts, and this differentiation is quite difficult at times. While it is possibly true that they appear as the result of some very slight irritation of the renal tissues, their presence is usually disregarded.

Hyaline casts are often found in the urine of healthy persons, probably as a result of errors in diet or drinking, or exercise. Under these conditions, they should quickly disappear. A too frequent reappearance, even under these circumstances, should arouse suspicion. On the other hand, these bodies are the first to appear in disease as an indication of commencing irritation or congestion of the renal tubules.

Granular casts, if present, will almost always lead to rejection on account of the well-known fact that they indicate more advanced lesions in the renal tissues.

The medical officers cannot fairly estimate the significance of these doubtful bodies in the urine, unless the reports are made by men whose ideas are harmonious with those held at the home office. All microscopical examinations are therefore made either at the home office by men trained for this work and with the most approved apparatus and facilities, or at certain points by selected representatives who have taken a course of instruction at the headquarters of the companies.

Microscopical examinations of the urine are required only in cases in which there is some indication or when the amount of insurance is large enough to warrant this extra precaution.

Note.—The methods and technique of uranalysis presented in these columns are, aside from a few modifications, recommended in its book of instructions to examiners by the company which the writer represents, and have been found most reliable and simple after many years of experiment and practice.

Attitude of the Medical Director Toward the Agency Department.—P. O. Gold sketches the attitude which, in his opinion, the medical director should assume toward the Agency Department. He points out that the medical director is dependent upon the agency department for his livelihood. Yet, he must be a restraining influence like the flywheel of an engine which, though turned by the motive power of the engine, restrains the same power. In the medical director's attitude toward the getting of business he should take into consideration, first, the company's interests, remembering not only the question of individual hazard, but also the class of business, the ability of the applicant to pay his premium, the territorial conditions, and the standing of his local examiner. It would be better for the company if more advances were made by the medical department and less by the agency department. The attitude of the medical director toward the agency department should be one of education. Errors of the agent should be immediately called to his attention to prevent a repetition. Loss to the company is thereby prevented, the agent appreciates it, and tries to prevent a similar mistake in the future; or if he does not he should be eliminated. —*Second Mid-Year Meeting of the Medical Section of the American Life Convention.*

The Value of Uranalysis at the Home Office.—James W. Guest, thinking that the heat and acid test is not wholly reliable when but traces of alumin are present in the urine, as medical director of the Commonwealth Insurance Company decided to adopt a "home office uranalysis." In putting this system into use, two serious obstacles presented themselves. First, Dr. Guest knew from his personal knowledge as an examiner that oftentimes only small quantities of urine could be secured from applicants, and that he could ask for only a very small amount of the specimens collected by the examiners for home office uranalysis. Second, that postage would become a large factor unless it could be reduced to a minimum. After experimenting for several days with office associates it was found that a thoroughly satisfactory uranalysis for both albumin and sugar could be made with only fifteen or twenty drops of urine. To meet the above requirements a glass dram vial filled with urine and a papier maché container weighed in all one and one-half ounces. The container required only one cent postage. However, two-cent postage, first class, was substituted, as after giving the one-cent postage a trial it was found that the specimens were delayed on account of being second class mail. The tests used are Roberts' solution for albumin and Haines' solution for sugar. Dr. Guest is of the opinion that the plan should be generally adopted.—*The Loncet-Clinic*, July 27, 1912.

Book Reviews.

Quain's Elements of Anatomy. Eleventh Edition. Editors: Edward Albert Schäfer, LL.D., Sc.D., M.D., F.R.S., Professor of Physiology and History in the University of Edinburgh; Johnson Symington, M.D., F.R.S., Professor of Anatomy in the Queen's University of Belfast; Thomas Hastie Bryce, M.A., M.D., Professor of Anatomy in the University of Glasgow. In Four Volumes. Vol. II., Part I.: Microscopic Anatomy. By E. A. Schäfer. With 1001 engravings and 21 colored plates. London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1912.

This eleventh edition of Quain's Anatomy, now being published, is in almost all respects an improvement on former editions. The only point in which the older editions were superior to the present was in the publication of bibliographies throughout the series. However, Schäfer's volume is complete in this respect also and is undoubtedly the fullest and best work on histology ever published in Great Britain. In fact, the work is almost too full, that is to say as a text book for students, for its size and the manner in which it is put together convey the impression that the author believes in the student making of histology a study separate from that of gross anatomy, whereas, for practical purposes they should be studied together. However, so far as the volume itself is concerned nothing but praise can be given. The illustrations of human tissues and organs are by Schäfer himself and are excellently reproduced. In writing on the protoplasm of the cell, mention is made of Hardy's work in this connection and in all instances the embryonic derivation of the various tissues and organs is described and discussed, a matter of very considerable importance. Professor Gustave Mann of Tulane University, New Orleans, deals with the structure of the vascular system and provides some very interesting reading with regard to the lymphatics. The book is worthy of the reputation of Professor Schäfer and this should be praise sufficient.

Surgical After-Treatment. A Manual of the Conduct of Surgical Convalescence. By L. R. G. Crandon, A.M., M.D., Assistant in Surgery at Harvard Medical School; Assistant Visiting Surgeon to the Boston City Hospital; Consulting Surgeon to Frost General Hospital and to Woonsocket Hospital; and Albert Ehrenfried, A.B., M.D., Assistant in Anatomy at Harvard Medical School; Surgeon to Mt. Sinai Hospital; Surgeon to Boston Consumptives' Hospital, etc. Second Edition, thoroughly revised. With 265 original illustrations. Price $6.00. Philadelphia and London: W. B. Saunders Company, 1912.

The cordial reception which greeted the first edition of this book cannot fail to be accorded to the revised form in which it now appears. The general practitioner no less than the surgeon can appreciate the importance of a safe guide in conducting the postoperative care of surgical cases. This book was written primarily for house surgeons in hospitals and general practitioners in communities which are not surgical centers. There is no reason why the general practitioner even in large cities should not be entrusted with the after-care of his surgical cases. He should be familiar with the management of postanesthetic vomiting, postoperative gastric dilatation, and with the virtues of the Fowler position, enteroclysis, etc. This volume presents in satisfying detail, with the aid of numerous illustrations, a description of the after-treatment for all of the common surgical operations. Such measures as massage, electrotherapy, *x*-rays, and radium therapy are accorded considerable attention. The subject of therapeutic immunization and vaccine therapy is presented in an admirable manner and with ample regard for the practical needs of the physician, by George F. Sanborn. The volume may be recommended without reserve as one supplying adequately a distinct need in the physician's library.

Symptoms and Their Interpretation. By James Mackenzie, M.D., LL.D., Aber. and Edin.; Lecturer on Cardiac Research, London Hospital; Physician to the Mount Vernon Hospital; Consulting Physician to the Victoria Hospital, Burnley; Author of "Diseases of the Heart." "The Study of the Pulse, Arterial, Venous, and Hepatic, and of the Movements of the Heart," etc. 2nd Edition. Price 7/10. London: Shaw & Sons, 1912.

This book has a value apart from the importance of its theme. Based solely upon the author's observations and not upon what others have written or copied from those who had gone before them, the subject-matter of this volume is eminently original. The statements are based upon what the author has noted at the bedside or in the consulting room and what in many instances he has been able to confirm at autopsy. The main theme is the author's conception of visceral pain. According to this theory the viscera are insensitive to stimulation, all so-called visceral pain being referred to the sensitive tissues of the external body wall. In detail the author discusses the various organic reflexes causing vomiting and dyspnea, the secretory, the cardiac, and the vasomotor and pilomotor reflexes; and the laws determining the nature of reflex symptoms. There are separate chapters on the preliminary examination of the patient, on symptoms of affections in the region of distribution of cerebrospinal nerves, on affections of the digestive organs, on the liver, gall-bladder and ducts, on the great and small intestine, on affections of the urinary system, on affections of the female pelvic organs, on peritonitis and peritoneal adhesions, on affections of the lungs and pleura, on affections of the circulatory system, and on the estimation of the value of symptoms. This work is epoch-making in its originality.

A Text-Book on Gynecology. By William Sisson Gardner, M.D., Professor of Gynecology, College of Physicians and Surgeons, Baltimore, Md. With one hundred and thirty-eight illustrations in text. New York and London: D. Appleton & Company, 1912.

In this work a greater amount of space is given to the diseases that are common and with which it is essential the student should be familiar. Many of the rare diseases are treated very briefly and the subjects that really belong to general surgery have been omitted. The limited time of the overcrowded medical student has been taken into consideration. The subjects are treated in a very concise manner, and if any fault is to be found it is in the lack of space given some of the subjects. Including the index the book has 286 pages; the type is large, a fact that medical students who read so much by artificial light will appreciate. We recommend the book to medical students but not to the general practitioner, who would find it too elementary.

Surgery of Deformities of the Face, Including Cleft Palate. By John B. Roberts, A.M., M.D., Professor of Surgery in the Philadelphia Polyclinic, Surgeon to the Methodist Hospital; Formerly Assistant Eye and Ear Surgeon to the Children's Hospital, and Demonstrator of Anatomy in the Philadelphia Dental College. Illustrated with 273 Figures. Price $3.00. New York: William Wood & Company, 1912.

The appointment to deliver the Mütter Lectures of the College of Physicians of Philadelphia for 1900 induced the author of this excellent treatise to give increased attention to the operative correction of facial deformities. This lectureship was established by Thomas D. Mütter, the Philadelphia teacher, who had played such an important part in the early history of plastic surgery. These lectures form the basis of the book. In the fifteen chapters, consisting of 259 pages, there are considered the development of plastic surgery, a survey of the anatomy of the face, characteristics of surgery of the face, the principles of plastic surgery of the face, gunpowder and local discolorations, tattooing, fistules, fissures, encephalocele, atrophy and hypertrophy, disfiguring skin diseases requiring surgical treatment, deformities of the mouth and lips, harelip and other facial clefts, cleft palate, cheiloplastic operations not connected with harelip and cleft palate, deformities of the external ear, deformities of the nose, rhinoplasty and deformities of the eyelids and eyeball. Any who may be called upon to treat any of the subjects above enumerated cannot afford to be without this volume. The book is well illustrated with diagrams, photographs, skiagrams, and many drawings which are of great aid in getting a more perfect understanding of the text.

The Local Incidence of Cancer. By Charles E. Green, F.R.S.E. Price, one shilling. Edinburgh and London: William Green & Sons, 1912.

The writer of this small brochure has taken pains to collect various statistics of cancer mortality in England and Scotland, and to examine the localities where cancer incidence and cancer mortality appeared either very much higher or lower than the average figures. He claims that the mortality was high in regions intersected by gulleys and valleys, and low in comparatively flat regions. He considers that the topography is not directly responsible for the difference in cancer incidence, but indirectly through its influence upon ventilation and the carrying away of the products of combustion of coal and gas. The brochure is certainly of interest, though, of course, it cannot be convincing from the very obscurity of the subject dealt with.

Society Reports.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held in Hartford, Conn., June 10, 11, 12, and 13, 1912.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. A. D. BLACKADER OF MONTREAL, CANADA, IN THE CHAIR.

Monday, June 10—First Day.

Presidential Address.—Dr. A. D. BLACKADER of Montreal, Canada, expressed his appreciation of the honor conferred upon him in electing him as their presiding officer; he felt that the honor was not for himself alone, but must be regarded as another instance of the generous and courteous spirit shown at all times by the profession in the United States to their confrères in the Dominion lying to the north of them. Dr. Blackader spoke of a phase of the climate in Canada, the advantages and disadvantages of the steady cold winter in the treatment of some forms of disease. While it must be admitted that the winter months were long and severe, yet many found the climate stimulating and with health-giving properties; the steadily severe, but dry cold, of northern Canada, and especially of the Laurentian plateau, conferred a vigor not to be obtained elsewhere. Only to a few perhaps was the thought of a sharp frosty air, and a temperature at zero, or many degrees below it, an inspiration. Unfortunately to most of them a cold temperature in southern regions was almost invariably associated with much moisture in the air, and it must be acknowledged that cold with moisture was extremely depressing to the general vitality and strongly predisposed to irritable conditions of the upper and lower respiratory tract. They had no stronger or hardier immigrants than the Norseman or Scotch Highlander. Cold climates in which the air was dry were still more stimulating and, provided that the body heat was maintained by warm clothing and a proper supply of food, a keen frosty air induced in the sufficiently vigorous the maximum physiological reaction with much increase of muscular energy, provided the cold was not so intense as to altogether overpower the resistance of the system. The effect of cold air on the body was twofold. First, there was an actual extraction of heat, which was rarely desirable, and so far as possible should be prevented. In cold air, the body lost heat to a slight extent by evaporation and it perhaps lost a little more by radiation, while by conduction the amount lost was often very great, and was dependent upon the rapidity of the movement of the air and the amount of moisture it contained. Much more important, however, from a therapeutic standpoint, than the mere abstraction of heat from the body, was the stimulating action of the cold on the delicate sentient nerves of the periphery. Under the effective stimulation of the cold air, both respiration and circulation were strengthened, oxidation was increased, and nutrition became more active. In addition to the action on the cutaneous nerves, a powerful stimulation was also conveyed to the medullary centers by the effect of cold air on the nasal mucous membrane. Cold had also remarkably stimulating action on the digestive system, provided it was not excessive. As a rule, the appetite and digestion were better in the cold dry days of winter than in warm weather. Cold also appeared to stimulate the blood forming organs. As a result of this stimulation to oxidation and nutrition, the innate resisting powers of the body against toxins and its ability to respond protectively to the assault of infection was greatly increased. The benefit to be obtained from cold, however, depended upon the power of the individual to react, and this power varied greatly with different individuals and appeared to be in a great measure dependent on vasomotor tone. Dr. Blackader's experience led him to the belief that all those who suffered from any interference with the free passage of air through the nostrils did not react well to cold temperatures and gained but little benefit during the winter season. Also in inflammatory conditions of the larynx and trachea cold air might act as an irritant and do harm. Individuals suffering from organic diseases of the circulation as a rule stood cold poorly. To benefit from a winter in the north the intestinal tract and the kidneys should be in good working order. Extreme cold was not desirable for those suffering from gout, arthritis, or neuritis. For those suffering from advanced degeneration of any organ, for those advanced in years, and for the very young, extreme cold might be distinctly harmful. It could not be too strongly emphasized that all the benefit to be derived from a residence in the north would depend on the completeness with which an outdoor life was lived. Cold of not too severe a character was of distinct advantage to children over three or four years of age and to those children who breathed freely through the nostrils. Many of his patients, children of tuberculous parents, who were anemic and who suffered from enlarged glands with impaired digestion, were greatly improved by a winter spent in the Laurentian plateau. No other place that he was acquainted with presented so many advantages as a winter resort, with a steady cold, dry climate, as the Laurentian plateau. The great depth of snow buried all impurities and any added refuse was quickly hidden and rendered harmless by a fresh snow covering. All noxious evacuations lay dormant until the spring, and were then quickly carried off by the rapid flow of water. The daily variation in temperature rarely exceeded 15 degrees.

Physiological Observations on Pike's Peak, Colorado, Made in the Summer of 1911.—Professor YANDELL HENDERSON of New Haven, Conn., said that the heart rate was somewhat accelerated even during rest, and greatly accelerated by exercise, but arterial pressure was not considerably changed. The hemorrhages formerly noted were a myth. Respiration was considerably augmented by even moderate exercise. The red corpuscles were increased 30 or 40 per cent.; the total volume of blood, however, was unchanged. The most important element of acclimatization to low barometric pressure was the development by the lungs of a capacity to secrete oxygen from the alveolar air into the blood, thus compensating in part for lessened diffusion because of the low oxygen pressure in the atmosphere (elevation, 14,147 feet).

High Altitude and the Blood.—Dr. W. A. CAMPBELL of Colorado Springs, Colo., read this paper and drew the following conclusions: (1) The study of the blood had been a difficult one, subject to many corrections, owing to the variation in its component parts in the daily walks of life. (2) The study of the blood changes at high altitudes was attended by many additional intricate problems owing to the changed climatic environments and the inaccessibility of places of observation. (3) Altitudes increased the erythrocytes, hemoglobin, and leucocytes, thereby furnishing three of the most important factors in the building up of a stronger resistance against the infectious diseases. (4) The heart acted faster and the pressure was lower which tended to strengthen the cardiac muscles just as exercise of the general muscular system strengthened the individual as a whole. Caution must be enjoined in the beginning that the muscles be not overworked. (5) The lack of oxygen and the consequent increased respiratory exchange caused a more rapid metamorphosis of tissue, thereby aiding materially in throwing off morbid processes. The same condition prevented stagnation of secretions and brought into action portions of the lung unused at lower altitudes. (6) A study of blood conditions at high altitudes ought to convince any unprejudiced, financially uninterested individual that altitude was not a fake. And, by the application of the knowledge gained in its study, many clinical cases could be selected that would be materially benefited by a change to a high altitude.

Dr. JUDSON DALAND of Philadelphia said that these questions had excited interest for years, and after hearing a discussion some years ago he and the late Dr. Solly determined to go to Pike's Peak and make some observations. Dr. Solly suffered no discomfort and was able to walk about freely and easily while he himself had cyanosis of the lips and a severe headache, which disappeared when he returned to Colorado Springs. They remained on the Peak for four hours and no especially bad effects were noticed in that time. Microscopically the number of red blood corpuscles was increased, but there was no morphological change in the blood. There was no apparent leucocytosis. Changes in the readings of the hematometer were so slight as to be insignificant. They had also made observations on two brothers, aged twenty and twenty-nine years respectively, who had become acclimated. It seemed to him that two important points were brought out: First, the value of physiological functioning on the part of the alveolar cells to secrete oxygen, and, secondly, that there was no leucocytosis. When one went to an altitude of more than 2,000 feet one experienced a most remarkable and extraordinary air hunger.

Dr. HOAGLAND of Colorado Springs said that the effect of high altitude on the blood was a subject of great importance. In experimenting with the blood on Pike's Peak, he had time and again noticed that when the timber line was passed half a dozen persons on the car would turn pale. He had seen the color return within two minutes and the individuals be able to eat. He had obseved many people from the East with valvular heart disease. Altitude helped certain cases of weakened heart muscle. When there was a defect in contractility, then any

change in altitude was contraindicated. In conditions of weak heart alone, patients did as well in high altitudes as elsewhere. The second point Dr. Hoagland wished to emphasize was that the impression in the United States that mortality from pneumonia was high in high altitudes was a false one. A comparison of statistics showed that the mortality was no higher. Many had insomnia on Pike's Peak. There was an increase in the capacity of the chest when one went to a high altitude. Dr. Hoagland said his chest measured 35 inches when he went to Colorado Springs, while now it measured 41 inches.

Dr. Fox C. Gardiner of Colorado Springs reported the case of a patient who had pneumonia and was sent down 5,000 feet, but did not improve. Dr. Sargeant, on his first trip, could not breathe well, but on his next trip he took a dose of calomel and had no difficulty in breathing. Dr. Gardiner said he agreed with what Dr. Hoagland had said in regard to heart trouble. He cited the case of a man who was told he could not live on account of heart trouble; this man went up 8,000 feet and lived for many years.

Dr. DeLancey Rochester of Buffalo, N. Y., said that altitude caused an increase in the percentage of hemoglobin and in the number of red and white blood cells. There was a dilatation of the peripheral capillaries. There was an increase in the polymorphonuclears, but not in the lymphocytes.

Dr. F. M. Pottenger of Monrovia, Cal., said there was a possibility of their drawing wrong conclusions from these physiological inquiries. The important point was that when they went higher there was an increase in the component parts of the blood and this was necessary to maintain the individual. Dr. Pottenger said he practised at a low level and received patients from higher levels and he found that the patients were benefited both ways. Clinically the best observations were those of Dr. Henderson, which referred to the development of the lung capacity to secrete oxygen from the alveolar air into the blood.

Dr. A. J. Richer of Ste. Agatha des Montes, Province of Quebec, said there was no doubt but that the blood changes were due to the struggle for adaptation. When sending a patient to a high altitude there was no doubt but that there resulted an extra amount of exercise in this effort at adaptation.

Dr. Carroll E. Edson of Denver, Colo., said that, when a splitting headache occurred, they should remember that frequently it was bilateral, and it would be interesting to know whether a case of frontal or bilateral headache was due to an unrecognized collection which drained from the frontal sinus. It was difficult to state whether this was purely a circulatory phenomenon. The question of secreting oxygen from the alveolar air into the blood had not been proven in his opinion. Could not the balance of oxygen be maintained in the blood by quickening the power of the right side of the heart?

Dr. A. W. Jayne of Denver, Colo., said that the observations made on the blood explained many things that hitherto they had been unable to prove clinically. He went to Colorado in the early eighties on account of his health and practised medicine at an altitude of from 9,000 to 11,000 feet. To his surprise he found that surgical wounds healed with great kindness, a large proportion by first intention. Fractures got well promptly. He had greater success in acute surgery than was ever seen in New York City. Good and quick recoveries were seen in all acute diseases. He could not explain these surprising results on purely physical grounds. Many cases of pneumonia at mining camps were fatal, but this was explained because of the unrestrained lives of the men, many of them developing pneumonia after a period of intoxication.

Dr. Robert H. Babcock of Chicago said that when a patient with heart disease asked him if it was advisable to go to a high altitude he did not know just what to answer. He usually answered, however, even when the patient had a manifest cardiac lesion, "Yes, if you keep quiet." He also told such patients that if they suffered from dyspnea and tachycardia to keep quiet for a few days or a week until they became accustomed to the altitude. In all probability they would not suffer after that.

Dr. Yandell Henderson of New Haven, Conn., said he did not think the bilateral headaches in these cases were due to sinus trouble. The critical line was from 6,000 to 10,000 feet. With regard to the term lymphocytes, that was Dr. Webb's. He was responsible for the idea of increasing the lymphocytosis as a factor in combating tuberculosis. In regard to the respiratory change, no more carbon dioxide was gotten rid of at a high altitude than below, but the intake of oxygen was greater; however, to get rid of it the patient had to work harder.

Dr. W. A. Campbell of Colorado Springs, Colo., in closing the discussion said he did not mention lymphocytes in his paper, but leucocytes. Polymorphonuclear leucocytes were what they wanted to develop. He agreed with what Dr. Pottenger said about physiological compensation. At sea level there seemed to be a portion of the economy that was not needed, a portion of the lungs and a portion of the circulatory system. At Colorado Springs, which was at a medium altitude, equilibrium was attained and the organs were not overtasked. Individuals who went there might complain of tachycardia and dyspnea and their fears were not allayed until their equilibrium was established. He had asked the man who ran the place on top of Pike's Peak about mountain sickness, and he told him that he suffered from it at times and that his remedy was bromo-seltzer.

Climatology as Practised by Hippocrates.—Dr. DeLancey Rochester of Buffalo read this paper. He said that his information in regard to Hippocrates had been culled from many sources, though most of it had come from the "Translation of Hippocrates' Work" by Francis Adams and from the copious notes which he gave in connection with this. There were many Asclepia or temples of health in Greece. Most of them were erected in the neighborhood of some medicinal spring. They were really sanatoria. Especially noted among them were two, one at Cnidos and one at Cos, and to these temples patients came in goodly numbers. At the entrance to the temple the devotee was subjected to purification and made to go through a regular course of bathing and massage; fomentations with decoctions of odoriferous herbs were also used. A total abstinence from food was at first prescribed, and later foods of various kinds were allowed. Every means that could be thought of was used for working upon the imagination of the sick, such as religious ceremonies of an imposing nature, accompanied by music, and whatever else could arouse the senses, conciliate the confidence, and in certain cases contribute to the amusement of the patient. From his forefathers Hippocrates inherited a distinguished situation in one of the most eminent hospitals, or temples of health then in existence, the Aslepion of Cos, where he must have enjoyed full access to all the treasures of observations, collected during many generations, and at the same time had an opportunity of assisting his own father in the management of the sick. Thus, from his youth, he must have been familiar with the principles of medicine, both in the abstract and the concrete.

Neurasthenia in the United States.—Dr. J. Madison Taylor of Philadelphia presented this communication. He said that neurasthenia, which was a state of morbid fatigability and susceptibility to exhaustion states and disease-causing agencies, was admittedly on the increase. To determine the underlying causes of this condition, which should lead to their mitigation or control, would prove of great economic value. A postulate was offered based on a mass of evidence to the effect that: *The fundamental agency in producing nervous instability or subversion of energies, was to be found in the peculiarities of climate hitherto inadequately appreciated*, and its corollary: omissions in observing conservative modes of life whereby the hurtfulness of adverse climatic conditions could be escaped. The United States were in a latitude similar to that of the Mediterranean basin; hence the summer was subtropical, with providentially cool winters. During the summer, periods of extreme, prostrating heat alternated with comfortable days. At all times (from May to September) there prevailed excessive, prolonged sunglare, which was determined to be the essential factor in "tropical neurasthenia," especially in blondes, among whom the majority of instances were said to occur. The inhabitants of the United States came originally largely from Northern Europe. For these and their descendants it was important to know whether among them neurasthenia was more common than among those from Southern Europe. Those individuals suffered most who exhibited least the physical characteristics or conformation necessary for survival in any climate for which they were not adapted by age-long evolution and selection. The tendency for blondes in successive generations to deteriorate in a hot, glaring environment was well determined. They showed a progressive lowering of tone and resisting powers in the central nervous system, a pitiless weakening of vital forces, simulating neurasthenia. Disintegration of these vital powers, physical, mental and moral, so necessary for sustained action, opened the door to divers hurtful agencies. Energy was a characteristic of peoples reared in cold, cloudy countries. In the tropics it was not only hurtful for all to be energetic, but made for manifold destructive changes in vital structures. Those who survived best

in the tropics were those most capable of indolence and quiet, with only spasmodic energizing. The relaxed, perspiring skin of the blonde under tropical temperatures was the same as in a prolonged hot bath, intensely weakening, impairing recuperative power and moral tone. The most serious factor, however, was excessive prolonged light, as shown by all physicists who had worked with the extra spectral rays, and these same rays existed in sunlight and were in excess during June and July, the months of suicides, homicides, and incidence of insanities. It was, then, reasonable to infer that undue exposure to summer light and heat in the United States must and did cause suffering proportional to the defects in the conformation needed. Doubtless the causes of neurasthenia were many and complex, but the one cited was, or seemed to be, at the foundation of many contributory factors. If the above postulate were sustained by further study, then were the remedial measures obvious and urgently needed. Methods of life (conservative personal hygiene) should be taught and enforced designed to meet these and similar exigencies. During the hottest portions of the summer (often so intense), it was the part of wisdom to adopt many of the customs found necessary in subtropical countries. These were in strict accord with universal experience of what was most compatible with the local climatic peculiarities to be reckoned with. Violations of these elements of conservative personal hygiene were met by swift and condign punishment in the tropics and subtropics. Among the needful customs were earlier rising and the devotion of one or two hours at midday to rest or sleep; cessation from active affairs between noon and early afternoon. Indeed, it had been proven that better economic results followed fewer hours of any kind of work. Long hours not only tired, but exhausted the individual. Tree-planting should be obligatory in all cities; shaded playgrounds were essential for young and old, so were abundant facilities for cool baths. Clothing should be used adapted to the temperature—heavy garments killed energy; food should be modified, and all devices employed to shade and cool houses—dark awnings, power-fans, etc.

Tuesday, June 11—Second Day.

Climatology in the Curriculum of the Medical Schools of the United States and Canada.—Dr. James M. Anders of Philadelphia said that the accumulated observations of the effects of climate in the treatment of various conditions and diseases abundantly proved that it was one of the most valuable resources of the physician. Medical literature examined in its relations to climatotherapy as a remedial agent, however, revealed the unwelcome fact that it had done but little more than maintain its place with undiminished reputation during the last half of a century. Those interested in the subject of medical climatology should have assigned to it its proper office among the curative and preventive measures. In 1904, the late Dr. S. E. Solly called the attention of this society to the question of establishing a systematic teaching of climatology in the medical schools, and, in order to determine the extent of special training at that time, he mailed a circular letter to all the medical colleges, to which thirty answers were received. Of these only seven stated that climatology was included in the curriculum, questions set, and books recommended. Following the example of Dr. Solly, Dr. Anders mailed a circular to all American medical colleges, 140 in number, with a view of ascertaining to what extent the movement then proposed to advance the teaching of climatology had succeeded during the intervening period of nine years. The following questions were propounded: "Is climatology included in the regular curriculum? If so, how many lectures are given; are they in a separate course or in connection with one or other subjects, and for which year's students? Are a certain number of questions regularly set in the final examinations; if so, how are the answers rated?" Of the 140 letters sent out, replies were received from 99 institutions. Twenty-two included climatology in the curriculum, as against seven out of a total of 30 answers received by Dr. Solly in 1904. Certain inferences might be safely drawn from the facts presented: (1) That the most striking positive evidence obtained by this inquiry went to show that the subject of medical climatology received too little recognition in their schools of medicine. (2) From the character of the responses received to the series of questions propounded, cooperation on the part of medical faculties and pedagogic authorities would be readily given to efforts to introduce the teaching of this branch into their institutions of medical learning. (3) That the American Climatological Association could do no better, no more useful work, than to foster and promote this movement, through a special committee and a well directed campaign of education, for its own credit as well as for that of the entire medical profession of America. (4) That the instruction to be given should be confined to the elementary principles of meterorology in the junior year, since this would be sufficient to enable the student to select suitable climates in clinical cases presenting an indication for this valuable remedial measure.

Dr. Guy Hinsdale of Hot Springs, Va., said that Dr. Anders' paper was a very timely one and that there was no more proper field of work for the Association than that of promoting the teaching of climatology in medical colleges. It was remarkable how students became interested in collateral branches of this kind. He had obtained much aid in teaching this subject from lantern slides furnished him by the University of Chicago and Tuft's Medical College; the latter collection of slides showed meteorological conditions particularly in reference to temperature, barometric pressure, humidity, and rainfall throughout the country. If medical colleges would allow four lectures together with eight quizzes and the handing out of printed lectures, it would be a good thing. The Marine Hospital Service published valuable reprints of papers written by surgeons in various parts of the world on climate and temperatures, the occurrence of hemorrhages at high altitudes, and kindred topics; these could be distributed to the students. The Association should pass recommendations as to how such a system of lectures should be developed and subjects should be assigned so that teachers could follow along systematic lines.

Dr. Carroll E. Edson of Denver, Colo., said that there were a number of colleges in the catalogues of which this subject was found. The giving of but four lectures would be inadequate excepting for the purpose of laying a foundation for further study. One could not give the student a clear idea of how climate affected the physical economy, heat production, and so on, in four lectures. In his experience he had found that the idea was prevalent that schools with good medical equipment did not give sufficient attention to those studies which served to lay the foundation for climatic therapy. A course of study such as was suggested by Dr. Anders and backed by the American climatological Association would be of great advantage.

Dr. Charles L. Minor of Asheville, N. C., said that unfortunately climatology was not a definite science and there was very little to teach about it. Meterology was not in the hands of the doctors. It would be heretical to say that climatology was but little worked out and no one could give a systematic series of lectures and teach very much.

Dr. James M. Anders of Philadelphia, in closing the discussion, said he agreed with Dr. Hinsdale that it was the legitimate function of the association to encourage the teaching of this branch of medical science in medical schools and, if the third year student was given a brief course in the elements of meteorology, he would have something which would serve as a basis on which to select suitable climate in various diseased conditions and which would be of major service. This latter aspect of the subject should be brought to their attention during the senior year. One who was properly qualified could extract sufficient in four or five lectures to lay the foundation for future work. The fact that the science of meteorology and climatology was not far advanced was no reason for refusing to give the student a foundation upon which to build.

Cardiac Syphilis with Special Reference to Aortic Aneurysm and Regurgitation, and the Value of the Wassermann Reaction in Determining Their Etiology and Treatment.—Dr. Robert H. Babcock of Chicago presented this paper. He said that the inestimable value of the Wassermann test for syphilis was shown not alone by its being a means of diagnosis but in its demonstration of the fact that treatment supposed to have eradicated the disease had in many cases only prevented the development of obvious lesions and thus lulled the victim into fancied security. Again, the test had served to clear up and establish the etiology of diseased conditions which had been more or less vaguely understood but which now could be affirmed with certainty. This was especially true of certain neuroses and of some cardiovascular conditions which could not be definitely determined as being due to lues even by the pathologists. Of these latter Dr. Babcock's paper dealt particularly with those two clinically recognizable results of mesaortitis, aneurysm, and regurgitation. Until possessed of this valuable aid in diagnosis, their ability to recognize syphilis of the myocardium was uncertain and rested mainly on the anamnesis or the discovery of suspicious lymph nodes or scars. It was likely, therefore, that many a case of cardic syphilis went unrecognized and hence missed the only means of therapy that could have offered a prospect of improvement. Only recently were

they beginning to realize that the spirochetæ might localize themselves exclusively and by selection in the heart muscle or in the walls of the aorta. The purpose of Dr. Babcock's paper was to emphasize the etiological importance of lues in mesaortitis and its two sequels, aortic regurgitation and aortic aneurysm. On looking over his case records since the close of 1909, he had found notes of 16 cases of aortic regurgitation of the vascular type. Of these 16 cases, 11 were submitted to the Wassermann test with a positive reaction in all. Of the remaining five a history of chancre was admitted in four while one was not questioned in regard to the possibility of lues and did not take the Wassermann test. Fifteen of the 16 cases accordingly could be attributed to syphilis, or a percentage of 93.7. During the same period of time (since the end of 1909) he had seen 10 cases of aortic aneurysm, the diagnosis in all being made by classical physical signs and confirmed by the skiagraph in those cases giving rise to any doubt concerning the accuracy of the diagnosis. Of these 10 cases, 5 gave a positive Wassermann reaction, 2 admitted syphilis, 2 gave no history and were not submitted to the Wassermann, while 1 gave a negative reaction. In other words, in 7 out of the 10 cases syphilis was clearly the etiological factor (70 per cent.). The result of mercurial treatment was not generally so marked as in regurgitation without saccular pouching of the vessel. It was apparent that no sort of medication was capable of restoring tissues destroyed by the spirochetæ; areas of fatty degeneration and fibrosis in the heart muscle could not be replaced by normal contractile elements, neither could the aortic valve nor the aortic coats become elastic. Gummata might be absorbed and nature given a chance to replace cellular by fibrous elements which might serve to strengthen or reinforce weak walls. From all points of view they were called on to institute vigorous antiluetic treatment as soon as they were convinced of the correctness of their etiological diagnosis. Intramuscular injections and inunctions were the only two practical methods of rapidly saturating the system with mercury. Salvarsan was highly powerful against the organism of syphilis, but in serious heart cases must be used, if at all, with caution; moreover it did not kill all the spirochetæ in the inaccessible recesses of the tissues. Therefore, salvarsan must be used more than once and must be supplemented by mercury over a long period. Finally treatment of whatever kind must be continued until a negative Wassermann reaction was obtained. The lesson to be drawn was that they should impress their patients with the imperative necessity of a vigorous and prolonged course of medication. If they would cure the cardiopathies due to syphilis, they must prevent their occurrence by attacking the infection early and keeping up the fight as long as a positive Wassermann reaction was obtained, for when aortic aneurysm, or regurgitation, or syphilis of the myocardium had been produced, they could only ameliorate and not eradicate the condition.

Dr. DeLancey Rochester of Buffalo, N. Y., said that they had made some interesting observations among their hospital cases. Out of twelve cases of aortic disease there were seven that gave the positive Wassermann reaction. Two of the seven gave a previous history of rheumatism. They now gave the Wassermann test in every cardiac case that entered their service. Dr. Rochester said he had obtained excellent results from intramuscular injections of mercury and he preferred this method rather than giving it by the mouth.

Dr. Charles Quimby of New York said that twenty years ago he had seen many cases of aortic disease with Dr. Loomis, who stated that he never knew a case of aortic disease occurring in an individual under thirty-five or forty years of age that was not syphilitic. When such patients presented themselves they were treated for syphilis. Only the week before he had seen a patient with syphilis of the aorta who was doing well under mercuric treatment, although the Wassermann test had been negative.

Dr. James M. Anders of Philadelphia, said that, as had been stated, syphilis undoubtedly showed a selective action for the myocardium. Both the myocardium and the pericardium might be secondarily involved by direct extension of the morbid process. The root of the aorta was the seat of syphilitic lesions which led to dilatations and aneurysms. Formerly he made his diagnosis in these cases by exclusion. Dr. Anders said he agreed with Dr. Babcock that cardiac syphilis was a late or tertiary manifestation of syphilis. After excluding rheumatism and occupation one might safely infer that syphilis was the causative factor in aortic regurgitation. In cases of angina pectoris, occurring in individuals over forty years of age, syphilis was the causative agent in the large majority of cases. Nearly all cases of sacculation of the aorta were also due to syphilis. He had recently seen a case where the Wassermann reaction was negative, but after giving salvarsan the reaction became positive. Probably the spirochetæ were too few to bring about the reaction.

Dr. Judson Daland of Philadelphia, said that, as to classification, he agreed with the point taken that aneurysm, especially sacculation, was not an ordinary dilatation. Dr. Daland laid particular stress on the predisposition of the spirochetæ to endanger the circulatory apparatus even more than the heart itself. They should bear in mind that syphilis was a very common cause of aortic disease, but that syphilis played a less common rôle as the causative factor in cardiac disease in this country than in Europe. The speaker also called attention to the frequency of cases with hypertension causing changes in the heart and circulatory system. Dr. Daland thought that the intravenous injection of salvarsan in these cases was dangerous, and said that if one examined into a number of deaths caused by salvarsan, it would be found that the majority of them occurred in those who had suffered from myocardial degeneration. There were a few cases where salvarsan might be injected into the gluteal muscles in small quantities, but even this he allowed with reluctance. One could not lay too much stress upon the possibility of death occurring either suddenly or a few days after the injection of the salvarsan in advanced cases of cardiac disease of syphilitic origin.

Dr. Arthur K. Stone of Boston, Mass., said that he had a number of specimens in which were demonstrated the presence of the spirochetæ in syphilitic aortitis. The spirochetæ were found in all cases of aortic disease beginning in the vasculature and extending into the heart. It had become a maxim with them that all such cases occurring after the fortieth year were syphilitic. It was better to say that a case was syphilitic and to go ahead on that basis than to trust to the Wassermann reaction unless one was very sure of the man who was doing the work. Dr. Stone said he had seen many cases improve rapidly and then suddenly go to pieces and autopsy showed that the lesion was too extensive for any treatment to have been of avail. He had used salvarsan in two advanced cases within the past six months with satisfactory results.

Dr. J. H. Elliott of Toronto, Canada, said he wished to ask Dr. Babcock what he thought of occupation as a factor in the production of these aneurysms. The pain caused by the intramuscular injection of salvarsan was severe but he could see no ill effects from its intravenous use.

Dr. Robert Babcock of Chicago, Ill., in closing the discussion, said that he had never seen a case of aortic aneurysm in which occupation was recognized as the sole cause, although he could readily understand theoretically that in old people with aortic sclerosis aneurysm might result from a strain. It was doubtful if the aortic wall could give way in young individuals without some underlying pathological factor being present. Strain might cause a dilatation of the aortic ring which might subsequently disappear. In cases attributed to strain there was probably some preexisting pathological process which acted in conjunction with the strain. In regard to what Dr. Anders said about negative results from the Wassermann test in young people, he questioned the accuracy of the reaction. The Wassermann reaction was reliable in its positiveness but not in its negativeness. No treatment would help all cases; one could not expect an area of degeneration of the heart to be replaced by normal elements. Vigorous treatment sometimes relieved these patients subjectively and gave a chance for possible restoration or compensation. Dr. Babcock said he was very conservative in the use of salvarsan in these cases. If the patient wished salvarsan used, the physician should have him sign a paper to the effect that he was acquainted with the dangers and had voluntarily submitted to this form of treatment.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Louisiana State Board of Medical Examiners.

May 30, 31, and June 1, 1912.

ANATOMY.

1. How many tarsal bones are there? Name them.
2. Describe briefly the cervical vertebræ.
3. Give origin and insertion of pectoralis minor, coracobrachialis, pronator radii teres, sartorius, and biceps.
4. Name the branches of abdominal aorta.

5. Give the relations of the femoral vessels in Scarpa's triangle.
6. Describe the blood supply of the cecum and vermiform appendix.
7. What are the relations to the deep epigastric artery of (*a*) an oblique inguinal hernia; (*b*) a direct inguinal hernia?
8. What is Gimbernat's ligament?
9. Tell briefly what you know about the fifth cranial nerve.
10. Name and describe briefly the membranes which surround the spinal cord.

PHYSIOLOGY.

1. Describe the anatomical and histological structure of (*a*) the neuronal cell-body; (*b*) the axone; (*c*) what is the function of each structure?
2. What is the tactile sense? (*a*) Where is it most acute; (*b*) what is its cognitional value; (*c*) what is its relation to the central nervous system?
3. Give the general characteristics of urine as to (*a*) quantity, (*b*) reaction, (*c*) specific gravity, (*d*) color. When do these vary?
4. Name the enzymes of the pancreatic juice and describe separately the part each plays in digestion.
5. What factors, chemical and physical, are concerned in gastric digestion?
6. Describe briefly the chemical changes, the thermal changes, the electric changes, changes of form, in muscular tissue when in a state of activity.
7. What is the character of contraction (*a*) in non-striated involuntary muscles, (*b*) in striated voluntary muscles; (*c*) give examples of each.
8. What are the functions of the blood plasma and of the blood corpuscles?
9. Describe the types of normal respiration and how influenced by (*a*) age, (*b*) sex, (*c*) race.
10. What forces are involved in the circulation of the blood in the arteries and in the capillaries?

CHEMISTRY.

1. What is the chemical composition of bone?
2. Mention six elements used in medicine and give their symbols and atomic weight.
3. Define (*a*) analysis, (*b*) synthesis, (*c*) cohesion, (*d*) chemical affinity.
4. Convert 67 degrees Fahrenheit into Centigrade.
5. What is the process termed when oxygen unites with another element?
6. Give a test for diacetic acid and state its clinical significance.
7. What is Ehrlich's diazo reaction and state its clinical significance.
8. Give a test for indican and state its clinical significance.
9. Give an emergency method of preparing ferric hydroxide for use in a case of poisoning by arsenic.
10. Give a test for HCl in the gastric contents.

THERAPEUTICS.

1. What are digestants? (*a*) Name the principal official digestants; (*b*) what are the therapeutic uses of each?
2. What are the indications and contraindications to the use of opium?
3. What is serum therapy and how would you treat a severe case of laryngeal diphtheria and what would be your prophylaxis in a suspected case of tetanus?
4. What are the therapeutic uses locally and internally of atropine sulphate?
5. Mention four ways in which antipyretics reduce body temperature.
6. How would you treat a case of arteriosclerosis?
7. Give the therapeutic uses of the different preparations of mercury.
8. How would you treat a case of syphilis in its different stages?
9. What are the indications and the contraindications in the use of ergot?
10. How would you treat a case of hookworm disease?

PHYSICAL DIAGNOSIS.

1. Define cyanosis and give its causes.
2. Define vocal fremitus and state its significance in pulmonary disease.
3. What are the essentially different sounds given by percussion over healthy lung?
4. What are the physical signs of pulmonary solidification?
5. In what condition does bronchial breathing take the place of vesicular breathing?
6. Differentiate organic and functional heart murmurs.
7. What are the causes and treatment of palpitation of the heart?
8. What are the causes of endocarditis?
9. Why is dyspnea caused by disorganization of the mitral valves?
10. What are the signs of impending death?

PATHOLOGY.

1. What post-mortem changes occur in the tissues?
2. What is the cause of a rise in body temperature? Explain the mechanism.
3. Define atrophy. Give the varieties of atrophy.
4. Differentiate fatty infiltration and fatty degeneration.
5. Define hyperemia, anemia, leukemia.
6. Explain what is meant by the terms physiologic and pathologic leucocytosis respectively. State whether a leucocytosis is present in the following diseases: typhoid fever, malarial fever, appendicitis, acute miliary tuberculosis.
7. What is an embolus? Mention frequent sources of emboli and state the sequels of embolism.
8. Describe, in the order of their occurrence, the cardinal signs of inflammation and explain them. State also the terminations of inflammation.
9. Describe the reparative processes following the fracture of a long bone.
10. What is the line of demarcation in gangrene?

ANSWERS.

ANATOMY.

1. There are seven tarsal bones: Os calcis; astragalus; cuboid; scaphoid; internal, middle, and external cuneiform.
2. The cervical vertebræ are smaller than those in the other regions, and can be distinguished from the others by the presence of a foramen in the transverse process. They have a small body which is concave above and convex below; long and narrow laminæ, short and bifid transverse processes, short and bifid spinous processes, and oblique articular processes. The peculiar cervical vertebræ are the first, second, and seventh.
3. *Pectoralis minor* arises from the third, fourth and fifth ribs at the costochondral articulation; and is inserted into the tip of the coracoid process of the scapula. *Coracobrachialis* arises from the coracoid process of the scapula; and is inserted into the middle of the inner surface and internal border of the shaft of the humerus. *Pronator radii teres* arises from the internal condyle of the humerus and from the inner side of the coronoid process of the ulna, and is inserted into the middle of the outer surface of the radius.

Sartorius arises from the anterior superior spine of the ilium; and is inserted into the upper part of the inner surface of the shaft of the tibia.

Biceps arises from upper margin of glenoid cavity and from the apex of the coracoid process of the scapula, and is inserted into the tuberosity of the radius.

4. The *branches of the abdominal aorta* are: Celiac axis, superior mesenteric, suprarenal, renal, spermatic (or ovarian), inferior mesenteric, lumbar, and sacra media.
5. At the base of Scarpa's triangle the femoral vein is internal to the femoral artery; at the apex of the triangle the vein is passing behind the artery.
6. The cecum is supplied by the ileocolic artery (branch of the superior mesenteric); this gives off the anterior and posterior ileocecal; of these, the anterior supplies the cecum, and the posterior supplies the appendix (chiefly by its branch the appendicular artery)
7. The deep epigastric artery is internal to an oblique inguinal hernia, and external to a direct inguinal hernia.
8. *Gimbernat's ligament* is a reflection of Poupart's ligament, from the spine of the pubis along the ileopectineal line.
9. FIFTH CRANIAL NERVE. *Superficial origin:* From the side of the pons Varolii. *Deep* (sensory root), from the medulla and upper part of cord; (motor root) from the floor of fourth ventricle and side of the aqueduct of Sylvius. *Exit:* The ophthalmic division, through the sphenoidal fissure; the superior maxillary division, through the foramen rotundum; the inferior maxillary division, through the foramen ovale. *Ophthalmic branch* distributed to conjunctiva, skin of upper eyelid, cornea, skin of forehead, and nose, lacrymal gland. *Superior maxillary*, to skin and conjunctiva of lower eyelid, nose, cheek, upper lip, upper teeth, and palate. *Inferior maxillary*, to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, and skin of lower

part of face. Also to muscles as indicated below. It supplies sensation to all the parts mentioned above; but, in addition, inferior maxillary supplies motion to the muscles of mastication, the mylohyoid, and anterior belly of the digastric.

10. Membranes of spinal cord. "The *Dura Mater* is the most external membrane, and is continuous with that investing the brain; but it does not form the endosteum of the vertebræ, nor has it any sinuses, but it is separated from the bones by areolar tissue and a plexus of veins. It is connected above with the edge of the foramen magnum; at the top of the sacrum it becomes impervious, and is continued as a slender cord to blend with the periosteum of the coccyx. This membrane gives sheaths to all the spinal nerves.

"The *Pia Mater* is less vascular, thicker, and more fibrous than that investing the brain. It has an external fibrous layer of longitudinal bundles having a fold, the *linea splendens,* dipping into the anterior fissure, and a smaller one passing into the posterior fissure. The pia mater ends in a slender cord, the *filum terminale,* which is within the prolongation of the dura mater. A process of pia mater, the *ligamentum denticulatum,* passes outward toward the dura, to which it is attached by twenty-two tooth-like processes situated between the origins of the spinal nerves; its pial origin is continuous, and lies between the anterior and posterior nerve-roots.

"The *Arachnoid* is placed outside the pia mater, and loosely invests the cord. The subarachnoid space of the cord is large, and is imperfectly divided by the *ligamentum denticulatum,* into an anterior and a posterior portion. The posterior portion is further subdivided by the *septum posticum,* which passes from the posterior fissure backward to the opposite part of the arachnoid, and contains the larger blood vessels. Trabeculæ also pass between the nerve-roots and the inner surface of the arachnoid, and between the posterior nerve-roots and the *septum posticum.*" *(Aids to Anatomy.)*

PHYSIOLOGY.

1. A *neuron* is a nerve cell with all its processes. The cells vary in size, but are generally large. They have one or more processes, a distinct nucleus, but no cell wall; the nucleus has a nucleolus; the cytoplasm is pigmented. The processes are the axis cylinder or axone, collaterals, and dendrites. The *axone* is usually a long protoplasmic process which carries an impulse away from the cell. It may be covered with a medullary sheath and a neurilemma. The function of the neuron (cell) is to receive or send out impulses, and to nourish the processes.

2. *Tactile sense* is the sense of touch; by it we become acquainted with the shape and consistency of bodies, their roughness or smoothness, hardness or softness, etc. It is most acute at the tip of the tongue. It depends upon the existence of nerves and nerve endings in the skin and other parts where the function exists. These nerves are, of course, in connection with the central nervous system; the sensation is conveyed to the brain. Irritating vapors and liquids are really appreciated by the tactile sense and not the sense of smell or taste.

3. The amount of urine voided in twenty-four hours is normally about fifty ounces; its reaction is acid; its specific gravity is from about 1015 to about 1025; its color is yellowish. The *quantity* is increased in winter and in diabetes, hysteria, epilepsy, and some kidney diseases; it is decreased in summer, in fevers, in gout, and certain diseases of the liver, kidneys, and heart. The *reaction* may become alkaline by a vegetable diet, or if the urine undergoes decomposition; also in cystitis, chlorosis, nervous diseases; it may become more acid in fevers, and diseases of liver, heart, or lungs, and in acid dyspepsia. The *specific gravity* is low in the presence of albumin, or polyuria; it is high when glucose is present. Naturally the specific gravity varies, with the quantity voided. The *color* is *light* in polyuria, neurotic conditions, and chronic nephritis; it is high colored in fevers and jaundice; yellowish-green in the presence of bile; white if chyle or pus is present; brownish, in the presence of decomposed blood; red, in the presence of blood; certain drugs will also cause changes in the color.

4. The *pancreatic* juice contains four ferments: (1) *Trypsin,* which changes proteids into peptones; (2) *Amylopsin,* which changes starch into dextrine and maltose; (3) *Steapsin,* which emulsifies and saponifies fats; and (4) a *curdling ferment,* which precipitates the casein of milk.

5. *Factors concerned in gastric digestion:* Movement of the stomach; innervation of stomach; secretions of stomach; and action of the hydrochloric acid and gastric ferments.

6. During contraction the following changes take place in a muscle:

(1) It becomes shorter and thicker, but the volume remains the same.
(2) It consumes oxygen.
(3) It sets free carbon dioxide.
(4) It forms sarcolactic acid.
(5) It becomes acid in reaction.
(6) It becomes more extensible and less elastic.
(7) There is an increase in heat production, and consequently a rise of temperature.
(8) The electrical reaction becomes relatively negative.

7. The contractions in *non-striated, involuntary muscles* are not under the control of the will; they are rhythmical, and are characterized by peristalsis. Example, the muscles in the walls of the intestines. In *striated, voluntary muscles,* the contractions are largely under the control of the will, are not rhythmical, and are not characterized by peristalsis. Example, the flexor muscles of the forearm.

8. Functions of the Blood: The *red blood cells* carry oxygen from the lungs to the tissues. The *white blood cells:* (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some part in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper proteid content of the blood plasma. The function of the *platelets* is not determined; it is possible that they take some part in the coagulation of the bood. The *plasma* conveys nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

9. There are two types of inspiration: (1) The Superior costal, or female type; and (2) the Inferior costal, abdominal, or male type. "In children, as well as in the adult male, under ordinary conditions, the diaphragm performs most of the work, and the movements of the abdomen are the only ones especially noticeable. . . . In the female the movements of the chest, particularly of its upper half, are habitually more prominent than those of the abdomen, and this difference in the mechanism of respiration is characteristic of the sexes." The protrusion of the abdominal wall, caused by the descent of the diaphragm, is very marked in children, and produces the abdominal type of respiration. Very careful and complete studies of women in and out of civilization, the lower portions of whose chests have never been compressed with corsets or with other devices calculated to prevent expansion of these parts, have demonstrated that the supposed respiratory difference in male and female does not exist naturally, and that when it is found it is due to the corset, and not to any peculiarity of sex. Indeed, if the male chest is encased in a corset the inferior costal type becomes changed at once into the superior costal. (From Raymond's *Physiology.)*

10. The circulation of the blood is regulated in the *arteries* by: (1) the elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) and the resistance in the capillaries. In the *capillaries* it is regulated by: (1) The action of the heart, (2) the action of the arteries.

CHEMISTRY.

1. Composition of bone:

Organic matter,	Gelatin and blood-vessels.	33	per cent.
Inorganic,	Phosphate of lime.....	51	"
	Carbonate "	11	"
	Fluoride of calcium.....	2	"
	Phosphate of magnesium	1	"
	Soda and sodium chloride	1	"

2. Oxygen, O., 16; chlorine, Cl., 35.5; iodine, I., 127; sulphur, S., 32; phosphorus, P., 31; and carbon, C., 12.

3. *Analysis* is the process by which a compound is split up into simpler compounds or into its constituent elements. *Synthesis* is the process by which a compound is built up out of elements or out of simpler compounds.

Cohesion is the force which unites (dissimilar) molecules.

Chemical affinity is the force which attracts atoms to each other, and causes them to unite to form a molecule.

4. $C.^\circ = \frac{5}{9}(F.^\circ - 32)$

$= \frac{5}{9}(67-32) = \frac{5}{9}$ of $35 = 19.5$

$\therefore 67^\circ$ F. $= 19.5^\circ$ C.

5. Oxidation.

6. *Test for diacetic acid:* To a few c.c. of the urine add a 10 per cent. solution of ferric chloride, drop by drop, until the phosphates are precipitated; then filter, and add some more ferric chloride. If diacetic acid is present, the urine becomes of a Bordeaux-red color, which disappears on boiling. *Diacetic acid occurs* in fevers, gastrointestinal disturbances, eclampsia, pernicious vomiting of pregnancy, and before diabetic coma.

7. *Ehrlich's diazo reaction:* Equal volumes of the reagent and of the urine are shaken together in a test-tube; one-half a c.c. of ammonia is floated on the mixture; a red band at the junction of the liquids denotes a positive reaction. The reagent consists of: (1) a saturated solution of sulphanilic acid in a mixture of 50 c.c. of hydrochloric acid and 950 c.c. of water; and (2) a 0.5 solution of sodium nitrite. When about to be used 1 c.c. of (2) is added to 40 c.c. of (1), and the mixture shaken.

The diagnostic value of the test is uncertain. Von Jaksch "disclaims for this test any clinical importance whatever." Others have claimed that the reaction is pathognomonic of typhoid; but it has been found in other diseases besides typhoid, such as phthisis, pneumonia, measles, scarlet fever, smallpox, and malaria.

8. *Test for indican in the urine:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chlorid, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so: but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

Indicanuria is found in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc. (From Witthaus's *Essentials of Chemistry.*)

9. Ferric hydroxide may be prepared rapidly by precipitating a solution of ferric sulphate with magnesia. The two following solutions should be kept in separate bottles; and, when needed, mix them, and administer.

(1) Liq. ferri tersulphatis ℥ij
Aquæ ℥vj
(2) Magnesiæ ℥iij
Aquæ ℥viij.

10. Test for hydrochloric acid in gastric contents: In a porcelain dish mix a few drops of filtered gastric contents with a few drops of Boas' reagent, then slowly evaporate over a flame. If hydrochloric acid is present, there will appear a rose-red color which fades on cooling. The reagent consists of 5 gm. of sublimed resorcinol and 3 gm. of cane sugar, in 100 c.c. of alcohol.

THERAPEUTICS.

1. *Digestants* are agents which aid in the process of digestion. The official digestants are: Hydrochloric acid, pepsin, pancreatin, and malt.

Hydrochloric acid is used in stomach conditions associated with inacidity or hypoacidity, such as cancer of the stomach, atrophy of the gastric glands, and sometimes in continued fevers.

Pepsin is indicated as an aid to gastric digestion in gastralgia, gastric cancer and ulcer, atonic dyspepsia, and the vomiting of pregnancy.

Pancreatin is indicated as an aid to digestion, and for the predigestion of food, in convalescence, in wasting diseases, and in intestinal dyspepsia.

Malt, a diastase prepared from malt is said to aid in the digestion of starch.

2. Opium. *Indications:* As an anodyne, in diarrhea, peritonitis, for internal hemorrhages, in mania and delirium tremens, in many respiratory affections, in diabetes, and to prevent or lessen shock. *Contraindications:* It should not be given to young children; nor should it be used in the second stage of pneumonia, alcoholism, cerebral congestion, or in bronchorrhea of old people.

3. *Serumtherapy* is the treatment of an infectious disease by a specific antiserum. *Laryngeal diphtheria* should be treated by the administration of diphtheria antitoxin, in doses of about 4,000 to 8,000 units. In a *suspected case of tetanus*, tetanus antitoxin should be administered in dose of about 2,000 units.

4. Atropine sulphate may be used *locally* to dilate the pupil, to paralyze accommodation, and as a sedative application in lumbago, inflammatory diseases of joints, etc. *Internally* it is given to check excessive secretion, to relax spasm, in shock and collapse to stimulate the vasomotor center, to stimulate intestinal peristalsis, and as an antidote for some poisons (such as physostigma, muscarin, hydrocyanic acid, chloroform, and opium).

5. (1) By abstracting heat from the body; (2) by producing perspiration (which is evaporated); (3) by dilating the vessels in the skin and so producing increased radiation; (4) by reducing the circulation.

6. *Treatment of arteriosclerosis:* Remove the cause if possible; forbid the use of alcohol; treat any disease that may be present (such as heart disease, nephritis, rheumatism, syphilis); diminish the meat eaten, and substitute vegetables where possible. Nitroglycerin, gr. 1/100; nitrites, diuretics, and laxatives have all been recommended. Hot baths, under proper supervision, exercise, and massage are indicated.

7. *Mercurial ointments* are used; as a parasiticide; as an application to sores; as an inunction in chronic inflammations, and enlarged lymphatic glands. The *yellow oxide,* for syphilitic and other sores, and in blepharitis. The *red oxide* for syphilitic and other sores, and as a parasiticide. The *nitrate* as a caustic for syphilitic warts and condylomata. *Mercury with chalk* and *blue mass* as laxative, cholagogue, and purgative; the latter, also, as diuretic, in syphilis. *Calomel* as laxative or purgative; in congested liver or stomach; in diarrhea, and as a diuretic. *Corrosive sublimate* as antiseptic and parasiticide; for itching, and syphilitic sores; in syphilis. The *iodides* chiefly for syphilis.

8. *Treatment of syphilis:* The management of the local sore consists in local cleanliness mainly. If the diagnosis is absolutely certain, mercury may be commenced at once, and may avert even secondary symptoms; but it is often advisable to wait till these appear before commencing specific treatment. Treatment consists in the early stages in the administration of one or other of the preparations of mercury. This can be given for long periods without producing salivation or diarrhea. Treatment must not be stopped when symptoms have disappeared, but must be continued for two or three years. Where symptoms are more urgent and a rapid effect is desired inunction of blue ointment ℥j daily, or hypodermic injection of corrosive sublimate gr. ⅛ every second day, may be practised, or calomel suspended in sterile oil may be injected into the gluteal muscles once a week. The condition of the mouth must be looked to and smoking should be forbidden if there are lesions in the mouth. In the tertiary stages, iodide of potassium to a great extent takes the place of mercury, but the two are often advantageously combined. Doses of from 5 to 20 grains thrice daily usually suffice, but in cerebral syphilis the drug must be rapidly pushed to even larger doses. In every case, besides treating the specific disease, the general health must be sedulously cared for. Salvarsan is now often used; it may he given subcutaneously, intravenously, or intramuscularly. It should be used with caution. (From Wheeler's *Handbook of Medicine.)*

9. Ergot. *Indications:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder, or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

Contraindications: During the first stage of labor, and in anemia of the brain or spinal cord.

10. The patient is placed on semi-starvation diet for half a day, and is then given from 2 to 10 grains of calomel; if the latter does not act freely Epsom salt may be given. When the bowels are thoroughly emptied some thymol in capsule must be given, the quantity depending upon the patient's age. An adult may take from 60 to 90 grains. The patient is again kept on a very restricted diet, with practically no liquids. After several hours a saline laxative may be administered. This treatment may be repeated (if necessary) in two weeks.

PHYSICAL DIAGNOSIS.

1. *Cyanosis* is a condition in which the skin is of a purplish hue from the presence of imperfectly oxygenated blood in the capillaries. *Causes:* Anything which interferes with the admission of air into the lungs, croup, retropharyngeal abscess, foreign bodies in air passages, pressure on air passages, pharyngitis, laryngitis, bronchitis, pleurisy, pneumonia, tuberculosis, emphysema, pericarditis, tumors of mediastinum, and some coal tar derivatives.

2. *Vocal fremitus* is a vibration due to speaking or crying, and conveyed from the surface of the chest to the hand of the examiner. It is *increased* in lobar pneumonia, phthisis, and bronchopneumonia; it is diminished or absent in pleural effusions, emphysema, atelectasis and pulmonary edema.

3. Dull, clear, and tympanitic.

4. In *pulmonary consolidation*, there are: diminished chest movement, increased vocal fremitus, absence of vesicular breathing, presence of tubular breathing, increased vocal resonance, bronchophony, and dullness on percussion.

5. Bronchial breathing replaces vesicular breathing in consolidation of the lung.

6. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease. *Organic murmurs* may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

7. Palpitation of the heart. *Causes:* Anemia, emotion, hysteria, mental anxiety, heart-strain, overexertion, dyspepsia, excessive and long continued use of alcohol, tobacco, coffee or tea, excessive sexual indulgence, menstrual disorders, and puberty. *Treatment:* Remove the cause, if possible; aromatic spirit of ammonia, or Hoffmann's anodyne, or trional, or potassium bromide and veratrum viride, or iron, quinine and strychnine may be given; a belladonna plaster applied to the precordium is beneficial.

8. *Causes of endocarditis:* Microorganisms, rheumatism, chorea, pneumonia, pleurisy, infectious fevers (scarlet fever, diphtheria, etc.), septicemia, pyemia, nephritis, gonorrhea, alcoholism, excessive muscular labor.

9. The *dyspnea* is the result of diminished oxygenation of the blood, as the result of lessened arterial pressure, increased venous pressure, congestion of the lungs, and back pressure from the left side of the heart.

10. *Signs of impending death:* The physical signs of a failing heart, rapid and feeble pulse, slow respiration, loss of consciousness, picking at the bed-clothes, frequent inquiry as to the time of day (or night); sometimes there is a peculiar odor to the breath. The Hippocratic facies is also characteristic; this includes "a sharp nose, hollow eyes, collapsed temples; the ears are cold and contracted, and their lobes turned out; the skin about the forehead is rough, distended and parched; and the whole face is brown, black, livid, or lead-colored."

PATHOLOGY.

1. *Post-mortem changes in tissues:* Rigor mortis; rise of temperature followed by fall of temperature; the arteries contract, and drive the blood into the veins; the red corpuscles split, letting out the hemoglobin; the tissues become stained; the blood tends to coagulate; putrefaction and decomposition take place. "The protoplasm tends to become granular; it sometimes increases in bulk, so that the cells look swollen; and in nucleated cells the nucleus often shrinks or entirely disappears. The cells ultimately break up into molecules of various sizes. In adipose tissue the cells diminish in size owing to the escape of the fluid fat, which diffuses itself throughout the surrounding structures. The fibers of connective tissue swell up, become opaque, and ultimately liquefy. In nerve-fibers the white substance of Schwann coagulates and collects into small drops within the neurilemma. Cartilage, bone, and hair resist the putrefactive process longer than any of the other tissues, and are the least altered by it." (From Green's *Pathology.)*

2. The normal temperature of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. Heat is *gained* to the body by (1) the muscles, during contraction; (2) the secreting glands; (3) the brain, during mental activity; and (4) by the ingestion of food and hot liquids.

Heat is *lost* to the body by (1) the skin, through evaporation, radiation, and conduction; (2) the lungs; and (3) the excretions (feces and urine).

Hence, a rise in body temperature may be due to a disturbance of any one or more of the three heat centers (the thermotactic, thermogenetic, and thermolytic); or to the presence of some toxic substances circulating in the blood; the mechanism is unknown.

3. *Atrophy* is decrease in the amount of tissue, owing to diminution in size (simple atrophy) or number (numerical atrophy) of the histological elements of which it is composed. There is also loss of weight, and impairment of function. *Varieties:* Simple and numerical (see above); also general and local.

4. In *fatty infiltration* the tissues contain fat brought from without; there is no change in the cell protoplasm, and such damage as the tissue undergoes is due to the mechanical pressure caused by the fat.

In *fatty degeneration* the cell protoplasm undergoes change; the fat is in the cells, and not between them.

5. *Anemia* denotes a condition in which there is reduction of the quantity or quality of the blood (generally used with reference to the red corpuscles). *Hyperemia* denotes excessive blood in a part. *Leukemia* is a condition in which the white blood corpuscles are increased in number, and is accompanied by pathological changes in the spleen, lymphatic glands, and bone marrow.

6. *Leucocytosis* is considered as *physiological* when it occurs in conditions which are normal or nearly so (such as during digestion, or pregnancy, after exercise); when it occurs in abnormal conditions, it is called *pathological.*

In typhoid, there is generally no leucocytosis; in malaria, none; in appendicitis there is a leucocytosis; in acute miliary tuberculosis, none.

7. An *embolism* is an intravascular obstruction from the lodgment of a foreign body. *Sources:* Thrombi, vegetations from the valves of the heart, portions of new growths, foreign bodies, fluid fat, parasites, pigment granules. *Sequels:* Infarction, irritation, infection, metastatic abscesses, gangrene, aneurysm.

8. The *cardinal signs of inflammation* are: Redness, swelling, pain, heat, and impaired function. One or more of these may be absent. "The *swelling* of the inflamed area is caused by the increased amount of the blood in the part and by the transudation of fluid into the tissues. The *redness* of an inflamed part is due to the presence of an amount of arterial blood larger than normal. The *increased temperature* is also due to the increase in the amount of blood and in the velocity of the circulation. The temperature of the inflamed part never exceeds that of the blood, though if there be fever it may be higher than normal. The *pain* is generally stated to be due to pressure by the exudation on the nerve-endings. Probably a good deal of the pain is due to the irritant action of the irritant, or of the fluids transuded, on the nerve-endings. The pain is sometimes referred to a distant part." (From Hewlett's *Pathology.)*

9. "The broken ends of the bone are rough and irregular, and the periosteum is torn more or less, but some portion usually remains as a bridge between the fragments. The soft structures in the neighborhood are lacerated, so that the parts are infiltrated with blood-clot, which fills up the spaces between the bone ends. As in repair of any other part, the blood-clot in a few hours is infiltrated with leucocytes, whose duty it is to absorb the clot. The connective-tissue cells in the surrounding parts proliferate, and the bone undergoes rarefying osteitis, so that the place of the blood-clot is taken by granulation tissue. The granulation tissue becomes calcified, and the calcified tissues ultimately replaced by bone. The periosteum plays a large part in the ossification of the new tissue. It becomes stripped up for some distance, hyperemic, and thickened. Granulation tissue is formed from it, and unites with that which has replaced the blood-clot. This mass binds the bone together and forms the *provisional* or *ensheathing callus,* which is subsequently ossified by the growth of the periosteal osteoblasts spreading over the mass. The medulla becomes plugged with granulation tissue or *internal callus,* and this, as well as the granulation tissue lying between the fragments of compact bone, becomes ossified, the bone cells of the compact tissue probably proliferating to take part in the repair." *(Aids to Surgery.)*

10. *The line of demarcation* is an inflammatory zone of living tissue at the border of a gangrenous area.

(To be concluded.)

The Batericidal Substance in Leucocytic Extract.—W. H. Manwaring has found that the bactericidal agent extracted from horse leucocytes is apparently precipitated quantitatively by full saturation with ammonium sulphate. The bactericidal agent is apparently precipitated by absolute alcohol, and is not rendered insoluble by a short contact with alcohol. The agent resembled in this feature certain enzymes which can be isolated and purified by alcoholic precipitation.—*Journal of Experimental Medicine.*

Miscellany.

"Lawyers and Phisitians."—This is the quaint title of an essay by a writer who signs himself "X." Montaigne is quoted as follows: "'Ferdinando, kinge of Spaine, sending certaine colonies into the Indies, provided wisely that no lawyers . . . should be carried thither, judging with Plato that lawyers and phisitians are an ill provision for any countrey.' Whence it would appear that, since 'Ferdinando, kinge of Spaine' did not prohibit the conveyance of physicians to his new colonies, he was of opinion that lawyers were the greater of the two ills." On the other hand, Cabbett believed that the lawyer "in defending the property of the feeble or the incautious against the attacks of the strong and the wiles of the crafty; in affording protection to innocence, and securing punishment to guilt; has in the affairs of men and on their condition in life a much more extensive and more powerful influence than can arise from the application of surgical or medical knowledge." The quotations serve as an introduction to the remarks by the author on the subject that has recently been enjoying the attention of a committee of the House of Commons, namely, the sale of patent medicines. It is urged that whereas physicians should demand a fitting reward for their services, they should temper this demand with discretion. "Perhaps it is because our daily task is with mankind in the moments of weakness that we are apt to realize the dependence of others upon us more vividly than we do the limitations of our functions and powers in relation to the outside world. In the sick room we are paramount. Discussion there has no place and the just assertion of authority is becoming. But, when our rights and privileges, as we conceive them, come into conflict with those of others, the mantle of mere authority that we sometimes assume falls from us." It is pointed out that all will agree that the sale of articles devised to further the commission of criminal offences and that the sale of articles by means of fraudulent pretences should be penalized. "But if we invoke the interference of the State to restrict the sale of gray powder and iron pills or aloetic aperients merely because certain manufacturers give their preparations attractive names and sell them more cheaply than a doctor can dispense them, we must, as a lawyer would say, show cause." Except in rare instances people do not take patent medicines when seriously ill and are quicker to detect arrant imposture than one imagines. Not all the claims put forward by the vendors of proprietary articles are extravagant. "If we are to set up arbitrary standards and condemn as quackery everything we can't explain (coming from unorthodox sources, *bien entendu*) we run two grave risks. We run the risk of discredit with the public when we have to revise our standards in the light of fresh knowledge; and we run the risk of having, in the alternative, as the lawyers say, to perpetuate, Chinese fashion, a face-saving orthodoxy." One "may be tempted to forget that there is often some truth in heresy and error in orthodoxy."—*The Universal Medical Record*, September, 1912.

Plato on Contract and Dispensary Practice.—F. W. Jollye notes that even in ancient days there were two classes of practitioners who were supposed to treat their patients differently according to whether they were club or private patients, and these two classes of medical men were consequently held in very different esteem by the public. Plato in one of his dialogues refers to the two sorts of doctors as follows: "The slave doctors run about and cure the slaves or wait for them in the dispensaries; practitioners of this sort never talk to their patients individually or let them talk about their own individual complaints. The slave doctor prescribes what mere experience suggests, as if he had exact knowledge, and when he has given his orders like a tryant, he makes off with equal assurance to some other servant who is ill, and so he relieves the master of the house of the care of his invalid slaves. But the other doctor, who is a freeman, attends and practises upon freemen; he carries his inquiries far back, and goes into the nature of the disorder; he enters into discourse with the patient and with his friends, thus at the same time getting information from the sick man and also instructing him as far as he is able, and he will not prescribe for him until he has first convinced him; at last, when he has more and more brought the patient under his persuasive influence, and set him on the road to health, he attempts to effect a cure. Now which is the better way of proceeding in a physician and a trainer? Is he better who accomplishes his end in a double way, or he who works in one way, and that the rude and inferior?"—*The Lancet*, September 28, 1912.

The Teaching of Medical Economics.—A. H. Madry believes that every medical school should give a course in medical economics. The future physician should be taught that while the acquisition of wealth should not be his dominating motive, the satisfaction of duty well done is *not* to be the sole recompense, and that he who discharges faithfully the duty entrusted to him deserves a financial reward commensurate at least in part with the labor performed. It is the failure of this adequate reward that is the real cause of inefficiency and unethical living among professional men. Too often the physician begins his career with high ideals and well equipped for his duties and responsibilities save for a knowledge of the value of his services. The want of this knowledge permits the confiscation of his earnings and compels him to turn his attention to speculative and commercial enterprises, or to launch out into the uncharted sea of irregular medicine. Proper instruction in economics will teach the future physician the conservation of resources that strengthen character, build professional reputation, and inspire self-confidence; and at the same time this instruction will enable him to give to the world the happiness and prosperity it has a right to expect from his labors.—*Journal of the Missouri State Medical Association*, September, 1912.

Seven-Inch Tires.—Seven-inch pneumatic tires are now being used on the rear wheels of the automobiles in the service of the Detroit Police Department, and after a test of about 5,000 miles the tires are in good condition.—*Automobile Topics.*

New York's 1913 Tags to Be Purple.—According to news from Albany another attempt is to be made to solve some of the license plate problems that have been bothering the State of New York for several years. Next year's plates have been contracted for, 90,500 pairs having been ordered. The background will be of dark, purple, with raised letters in white. Each plate will bear "1913" and if for a motor truck will bear in addition the word "Commercial." The latter change has been made in order to prevent the use of the $5 commercial car license for pleasure cars, licenses for which cost from $5 to $25.—*Automobile Topics.*

THE SYPHILITIC PSYCHOSES.

BY FRANCIS M. BARNES, JR., M.D.,

WASHINGTON, D. C.

CLINICAL DIRECTOR, GOVERNMENT HOSPITAL FOR THE INSANE AND INSTRUCTOR IN PSYCHIATRY AND NEUROLOGY, GEORGE WASHINGTON UNIVERSITY.

"SYPHILIS is one of the most important etiological moments in psychopathology." This poignant statement made by such an experienced observer as Ziehen[1] merits the most attentive and careful thought on the part of all medical men and especially of those interested in psychiatry and neurology. During the early centuries following the spread of the Neapolitan sickness northward throughout continental Europe, sporadic mention of the possibility of syphilitic lesions within the central nervous system is met with in the literature. Under the sway of the doubt of the authoritative Hunter medical opinion veered from this trend until the work of Virchow and Hübner toward the end of the nineteenth century conclusively demonstrated that syphilis of the internal organs, of the brain, was a definitely recognizable pathological condition. Following this period advances in accurate knowledge of disease dependent upon this infection were comparatively slow until within the past few years, during which time developments in biological methods have rendered our progress tumultuous. Close upon the serological test of Wassermann follows the cutaneous reaction of Noguchi, which, though but recently in the field, bids fair to offer even more delicate aid than the method of complement fixation.

Such advances in our ability to recognize the existence of a latent, though possibly potentially virulent syphilitic infection, have obviously served to attract a vast amount of attention and profitable study toward the enormous pathological potential of syphilis and particularly toward those abnormalities of function associated with syphilitic lesions of the central nervous system, especially the mental disorders. So great has been the zeal in this latter direction that at times it is quite apparently forgotten that in dealing with such a widespread disease as syphilis, mental disorder occurring in a syphilitic does not necessarily mean that such mental disorder is a result of the syphilis, the question of coincidences as well as cause must receive due and proportionate attention.

An idea which is rapidly gaining currency is that syphilis, particularly syphilis involving the central nervous system, is becoming more prevalent. While statistics tend to bear out this belief, and it is a matter of common knowledge that such evidence is notoriously unreliable concerning this disease, it must not be forgotten that our added diagnostic ability may, in part at least, explain the apparent increased incidence of the infection and its subsequent manifestations. It is, in fact, noted that syphilitic diseases of the central nervous system are more often observed than formerly, whereas the malignant form of syphilis, particularly that affecting the cutaneous and skeletal tissues, is becoming less frequent. From this the question has been raised (Graves[2]) whether this infrequency of the latter form of malignant syphilis does not indicate that our population is acquiring a relative immunity from such forms because of the general syphilization of the race, this immunity being acquired at the expense of other structures of the body and especially the nervous system. But may we not find an explanation for this along broader avenues of approach? Cannot the application of the principle of biological racial differentiation be of aid here as well as in the study of the development of mental disorders in general? History shows that mental disorders in a given race increase in frequency of occurrence in direct proportion to the progress of biological differentiation—the increment is not a steady one, but rather expresses itself in the form of a curve, the lower levels representing the periods of heightened physical development during which the incidence of mental alienation is low, while the peaks indicate epochs of intense organization and specialization with the logical concomitant, increased mental stress and its associated natural result, more frequent mental breakdown. If there is any justification for the belief so often expressed, that syphilization and civilization run in parallel courses, we should not be surprised to find its proof at the present day. In brief, then, it would apear that we may expect the psychotic moment to become intensified when the pressure of activity is unequally distributed and is associated with imperfect or incomplete development and asymmetry or disharmonies in individual make-up. It appears very probable that in just this sort of ontogenetic defect we may find a partial answer to the question—why is it that one syphilitic develops, as a result of the infection, a mental disorder, while a second does not? One explanation has been sought in the postulation of an especial strain of syphilitic virus which possesses a particular affinity for nervous tissue, but the assumption of a *lues nervosa* has not received sufficient or convincing substantiation (Hübner[3]). It is very patent that aside from the syphilitic virus there must be other factors which are coactive determinants in the production of the psychosis. From analogy, perhaps, it becomes almost as obvious that here must be considered principally the mental make-up upon which the syphilis has become a modifying factor—the soil upon which the seed has fallen. It has been observed (E. Meyer[4]), that the symptomatology of certain nervous system disorders is made more intense by a subsequently acquired syphilis. We know, too, that there are constitutional psychopathies which predispose the individual to frank mental upsets which do not

occur in more normally constituted mental organizations under similarly unfavorable circumstances. Quite recently Czarnicckí[5] has observed that the symptomatology of dementia precox may be markedly modified by a superimposed cerebral syphilis as somewhat similarly Graeter[6] has demonstrated clearly the active rôle of alcohol in bringing into full bloom a latent precox. In the foregoing particular reference is made to the effects of an acquired lues. But also our appreciation of the ravages of this disease among the progeny of syphilitic antecedents is gaining ground in the medical mind. The more evident signs of an inherited lues, such as Hutchinson's teeth, rhagades, snuffles, interstitial keratitis and the like, are no longer the only criteria upon which judgment may rest. We now recognize that syphilis in the parents may be the cause of more generalized deviations from the normal in the progeny, the organism, as a whole or in certain particular respects, shows marks of weakness revealed in both physical and mental characters showing evidences of varying grades of imperfect and incomplete developmental growth or disharmonies and asymmetries expressive of illy balanced, one-sided products. The *Treponema pallidum* is no respecter of age, sex, or class, and, taking into consideration this markedly deleterious influence which it may exert upon the progeny, it is easily to be seen that the rôle which it plays in the fertilization of the soil from which mental disorders of varied types may take root and flourish is a leading one among the etiological factors in psychical disorders.

With the specific laboratory methods which we have as diagnostic aids it might appear at first glance that the recognition of a syphilitic process active within the tissues of the central nervous system was merely a matter of technique. Only too frequently the opposite state of affairs exists, and particularly in affections of the brain which make themselves known in more veiled forms through psychical manifestations than by physical signs. The internists have taught us that syphilis has but little originality, that it is the imitator *par excellence,* but it is only recently that this has been more extensively recognized by those interested in mental medicine, and that it has been appreciated that there is no mental symptom-complex which may not owe its existence to a syphilitic infection. In dealing with mental disorders, the psychiatrist has to face an entirely different problem from that which confronts the surgeon who meets with a case of appendiceal inflammation. To the contrary, he has to deal with processes which do not permit of immediate examination, and consequently it is largely by deduction derived from observed outward manifestations of cerebral activity that conclusions may be drawn. In the past it has been customary to recognize correctly those forms of cerebral syphilis with which occur the more prominent physical signs such as are dependent upon the more circumscribed and focal lesions, particular stress having been laid upon the occurrence of the epileptoid attack or its equivalent varying period of lowering of conscious threshold. The mental symptoms accompanying such conditions have received but scant attention, as a rule being looked upon as the unimportant and variable accompaniments of the more frequent, more evident and more tangible neurological disturbances. It certainly has not been so well appreciated that mental disturbances of varied types may be associated with cerebral syphilis when the focal signs may be entirely absent or may only occur at a time when the disease is clinically far advanced, thus assuming a rôle of secondary importance. More recent studies of the direct or remote effects of syphilis upon the functions of the central nervous system have shown that many of our former conceptions and conclusions must be altered and some entirely discarded. Further observation is needed before generalizations may be reformulated and at the same time by a more careful study of individual cases, there is a greater possibility that, should there be any characteristic symptom-complex expressive of the different pathological types of cerebral syphilis, it may be recognized and given definite form.

It may be well at this point to mention briefly the various mental symptom-complexes that in the past have been described as characteristic of cerebral syphilis. The principal types recognizable to-day were set forth in very good clinical descriptions nearly half a century ago by Wille[7] and it is largely due to the more recently forced recognition of the pathological potential of syphilis, acting upon the central nervous system to produce disturbances of function that the term "syphilitic psychosis" has come to occupy its present prominent position. It has, as it were, within the past few years, been *re*discovered. It is quite apparent, also, that not too definite or fixed limitations have enclosed the group of cases thus rubricated. Here, as in every opinion based upon unsatisfactory observations, the greatest diversity obtains. On the one hand, by some, disease pictures are described as characteristic of cerebral lues; on the other, it is denied with equal decisiveness that there exists any such symptom-complex and it is asserted that there is absolutely nothing characteristic unless it may be the banality of the ultimately resulting demential process. However, to express briefly our conceptions of the etiological rôle of syphilis in the production of mental disorder, without restriction to any particular or supposedly characteristic type of psychotic disturbance, the term syphilitic psychosis possesses a definite value.

Among the earlier works attempts to delineate a characteristic abnormal symptom-complex dependent upon cerebral syphilis resulted in the description of certain depressive and anxiety states, *e.g.* syphilophobia or a more generalized hypochondria, which were to be looked upon as prodromal phases of the syphilitic psychosis, the concluding picture of the series being a progressive deterioration. Besides this hypochondriacal introduction, it was recognized (Wille[7]) that the ultimate dementia might be preceded by an excitement, a delirium, or mania. The important point is that these abnormal mental states presenting themselves early in the disease were looked upon as the initial symptoms, only stages in a developing picture, and yet an attempt was made to segregate them as separate types of mental disorder characteristic of syphilitic processes involving the brain. Thus it was that the terms syphilitic melancholia, hypochrondria, paranoia, amentia, and dementia had their origin, the last being found so frequently in brain syphilis that almost all writers agreed that it was the characteristic symptom of all mental disorders associated with syphilitic alterations in the brain. By simply modernizing the above terminology and making a few slight alterations it will be found that a practically similar grouping under subheadings is in use to-day.[8]

A more definite tendency in this direction is evidenced in the syphilitic neurasthenia described by

Jolly[9], although he, too, recognized that this neurastheniform reaction often paved the way for more or less serious forms of mental disease. Although placing especial stress upon these psychoneurotic states, Jolly likewise recognizes the other types of mental disorder which may accompany luetic infection, that is, the paranoid, amential and manic or delirioid states, speaking of these as the more severe symptom-complexes. We do not have to deal here with mild, depressive reactive types of mental disturbance developing in persons at the time of primal awareness of luetic infection, but rather with those more aggravated states, during which there are complaints of headaches, transient and ephemeral confusional periods, fainting sensations, difficulty in recalling words and events, fleeting pains generalized in distribution, numbness in legs or general feeling of fatigue and exhaustion—the neurasthenic syndrome. There is quite apparently reasonable cause for doubting the existence of any such definite symptom-complex bearing a causal relation to syphilis, excepting in so far as it may occur as an introductory phase, as above indicated. It is, indeed, in this instance a difficult task to separate coincidence from cause. An outspoken neurasthenic attack in an individual having a predisposing tendency and an asymmetrical mental organization may no doubt be precipitated by a syphilitic infection. But the syphilis itself is not directly the prime factor—it is but secondary, merely an exciting agent. On the other hand, it is by no means infrequent that we meet with a neurasthenic onset in cases of cerebral syphilis and paresis. The examination of the spinal fluid and blood serum has been a reason for the numerical reduction of diagnosis of neurasthenia in the incipient states of such conditions. To separate a group of symptoms which occurs as a prologue to a definite disease, to speak of this as an entity under the term "syphilitic neurasthenia" can, however, accomplish no possible good. Such attempts to single out certain prominent features in the varied and multiform symptomatology of those psychotic states arising as a result of, or at least in connection with, luetic cerebral lesions, and to group these into the formation of a clinically recognizable symptom-complex have not been infrequent.

However, the classification of the different clinical manifestations of brain syphilis is not a matter of prime importance, so that we can afford to lay this aside for the moment and turn to a consideration of our ability to recognize that a given mental disorder is dependent upon syphilis. The difficulty in distinguishing coincidence from cause has been mentioned. What differentially diagnostic data do we possess that may aid us in this regard? With those mental diseases which are associated with gross destructive lesions of the brain, the diagnosis may be made with a feeling of greater security and accuracy. Yet even in connection with that paradigm of organic disease, paresis, we have recently come to recognize many of the formerly unappreciated difficulties which confront the clinician, and we have been surprised to find how great our error has been in this one type. Although it may be true that there are several forms of what may be spoken of as the pure type, wherein a reasonably certain diagnosis may be made, a still greater number remain obscured by their close resemblance to other forms of mental disorder of functional or non-specific organic character. Mental disorders developing within the devolutional epoch, those dependent upon arteriosclerosis and senile changes offer heretofore unsuspected difficulties in differentiation. In addition it is found that syphilis of the brain may occur in an individual in combination with or superimposed upon another mental disease, such as dementia precox. In other communications[10] detailed case records illustrating these various difficulties have been presented with emphasis upon the fact that often the solution of the problem must be of necessity turned over to the pathologist.

However, certain criteria have been set up to aid the recognition of psychotic states originating upon a syphilitic basis, which may be briefly reviewed to advantage. In correlation with the anatomical findings, it is thought that the mental disorders associated with the acute and subacute meningoencephalitic forms of cerebral syphilis are much better recognized clinically than are the more chronic types. The latter are more frequently mistaken for arteriosclerotic psychoses or paresis. This may be because many of the simple demential forms occur as an expression of the chronic meningoencephalitis. When one recalls the great variety of anatomical lesions which may be produced by syphilis in the central nervous system, inflammations of the membranes, especially of the base, gummatous formations and the very frequent vascular changes, it might be expected that from such anatomical substrata multiform clinical manifestations might arise. Also, it might be expected that attempts to correlate the anatomical and clinical findings would be met with great difficulties and uncertainty. Krause[11] believes that with the basal type of brain syphilis the mental symptoms are of secondary importance and occur at a comparatively late period in the disease. With the meningoencephalitic forms involving primarily the convexity the psychical symptoms appear early—there are stupidity, confusion, sleepiness (sopor), delirium, with rapid transition into dementia. Also, the course may be more chronic, the dementia appearing later. Irritative signs are characteristic of this localization. The arterial forms are, like the former two, associated with headache; fainting and stupid episodes occur. On the mental side there is to be noted a decrease of mental activity, irritability with tearful affect changes. The alternation from periods of clear consciousness to those of death-like coma and the half waking, half dreaming states often associated with motor activity are looked upon by some as very characteristic of the arterial form.

Although such correlation may be found to exist in many cases, it must not be forgotten that the lesions of cerebral syphilis are not necessarily, and often are not, in fact, of one given variety; there may be combinations and mixtures of the several types. This is clearly stated by Mott[12] when he says that active syphilitic meningitis, arteritis, and gummata all may occur simultaneously, successively or progressively over the whole cerebrospinal axis. Surely one may not confidently anticipate a clear-cut symptomatological expression of such an anatomical *mêlange*. From the purely clinical standpoint the following features are considered of importance in this diagnosis. Firstly, in the course of the disease are seen distinctive features—the prolonged prodromal stages, the long duration, the varying progress, and the long remissions. As compared with other demential processes, there is a greater degree of preservation of the personality with retention of a fair amount of autocritical ability. Also, orientation is not greatly impaired as in the more

generalized deteriorating psychoses, such as senile dementia and paresis. Memory defects, especially for recent occurrences, in some cases are quite prominent. A diminution in attention may no doubt explain in part this defect, and also, as well, the observation that these patients as a rule do not acquire new ideas. The defects when noted are prone to occur in lacunar fashion and affect certain spheres more markedly than others, the demential process being more elective in its attack rather than lowering intelligence as a whole. The affect is possibly capricious, unstable—depression, excitement, apathy, and indifference may alternate rapidly. Somnolent, drowsy, semicomatose conditions of consciousness which are highly significant are not uncommonly observed from which, after varying periods, the individual may emerge into an approximately normal state of uncertain duration—a remission. Hallucinations and delusions may dominate the picture or occur sporadically, the content of the latter being not infrequently of a paranoid character, the hallucinations often lending support to the persecutory beliefs. Accompanying these psychic abnormalities are to be noted the many motor disturbances which follow in the train of variously located focal lesions.

The differential diagnosis between paresis and its imitator—diffuse cerebral syphilis, or syphilitic pseudoparesis—has recently received abundant attention and needs no detailed mention here. The distinction must in the last analysis very frequently be left to the pathologist. Clinically the differentiation is in some instances quite impossible. Even the serological examinations of the blood serum and the results of spinal puncture may offer insufficient data on which a final decision may rest. Now that this difficulty is more fully appreciated and the clinical similarity of the two conditions are kept more constantly in mind, it is but natural that errors should become less frequent than formerly.

The foregoing presentation of some of the clinical difficulties associated with the recognition of mental disorder dependent upon cerebral syphilis brings to light one general need, namely, that there is necessary for the more accurate knowledge of these mental disorders more definitely delimited and concise clinical descriptions, not alone of the syphilitic psychoses, but likewise of those included within the terms arteriosclerotic and senile dementias. We are possibly too prone to dodge the issue by keeping before the mind what may be called a type case and blanketing all apparently insignificant variations from this type under such convenient phrases as atypical, allied to, etc. It is just these so-called atypical features that should merit the closest attention, for by such intensive study we stand to gain a closer insight into the underlying process.

In considering the possibility of syphilitic etiology in the case of one suffering from mental disorder, the following points should be borne in mind:

1. There is no mental symptom-complex characteristic of syphilitic disease of the nervous system.

2. Many types of psychoses may be simulated by mental disorders caused by syphilis.

3. Cerebral syphilis may develop in a brain already affected with mental disorder and may occur in conjunction with other organic diseases of the brain.

4. Paralysis, paresis, and convulsive episodes may be absent in cases when mental disturbance is due to syphilis.

5. The differential diagnosis *intra vitam* is frequently difficult and often impossible.

SURGICAL PSYCHOSES.

By J. EWING MEARS, M.D.,

PHILADELPHIA.

WITH some misgivings as to the correctness of the title chosen, I desire to place on record several cases which, in my earlier surgical experience came under my treatment. They possessed interest possibly, in a neuropathic sense rather more than from a surgical viewpoint; their treatment, however, belonged to the surgeon, and for this reason they may be properly classed as surgical in character. They illustrate also the methods of treatment employed nearly two score years ago, and as well, in their varied features, they assisted to build good foundations on which some of the popular and absorbing creeds of the modern days have erected their stupendous structures of fantastic beliefs and practices.

Differ as we may in opinion with the followers of these schools of belief, real or fancied, and condemn as we must the harmful influences exerted, not only upon the individual, but upon the community, by their practice, we are constrained to believe that the person, male or female, especially the latter, who seriously lives in the belief that he or she is *sick*, is to all intents and purposes, sick, mentally sick, and is a legitimate subject for the most skillful methods of treatment in the power of the most learned and most observant practitioner of scientific medicine to administer. In any case and under all conditions treatment based upon erroneous diagnosis is disastrous, alike to the patient and to the disciple of medicine. To the former the failure of beneficial results makes them an easy prey to the alluring promises of the nostrum venders, professional and lay, who fill the world with their panaceas, banking in more than one way upon the credulity of the victim, whose faith, once shattered in the effort of an honest medical profession, refuses to accept its dogmas or to be placed again under its protecting ægis.

In the summer months of a year now gone two

score, I was asked to see the patient of an eminent physician who was spending the season abroad. I found the patient to be a young lady of some eighteen years residing in an attractive suburban home, enjoying all of the luxuries and comforts that the wealth of her parents could provide. The history given to me at the time of my visit was to the effect that for a period of seventeen months she had been confined to her bed suffering from an abdominal tumor and from a flexed condition of the left knee joint, the limb involved being on the same side as the abdominal swelling. There was no history of pain and suffering located either in the tumor or in the affected joint. The tumor when recognized occupied the left ovarian region and had increased but little, if any, in size since its discovery. The state of flexion in the knee joint had come on gradually and was unaccompanied by any increase in size of the joint—it exhibited simply a state of ankylosis, which could not be influenced by the efforts, apparently made by the patient. The facies of the patient was that indicating a normal state of health—nutrition did not seem to be impaired.

A disturbed nervous condition had, I was informed, ushered in the state of invalidism, but the symptoms had largely subsided under the treatment by bed rest and possibly, by remedies directed to the condition present. The respiratory and circulatory systems were in normal state and the functions of all organs were in harmony with the life of inaction which the patient had led for so long a period of time. In the quick movements of body and the manner of speech there could be detected evidences of a perturbed nervous condition, which may have been somewhat due to the presence of a strange medical adviser.

An examination of the abdominal enlargement revealed the presence of a circumscribed swelling about the size of the ordinary grapefruit, firm and immovable. Apparently, the overlying abdominal wall was involved in the mass. Deep inspiration and forced expiration caused the swelling to move synchronously with the movement of the superincumbent muscular walls of the abdomen. The slight effort at percussion, which the resisting efforts of the patient permitted, did not elicit any conditions of fluctuation. None but the gentlest manipulation was permitted by the patient, making it quite impossible by either auscultation or percussion to derive any very positive information as to the character of the apparent growth.

An examination of the flexed knee-joint showed a state of flexion at nearly a degree beyond a right angle. Compared with the joint of the right limb there was no evidence of difference in size beyond the condition of asymmetry found so frequently to exist between the right and left lower extremities of the anatomically normal individual; there was no pain produced by pressure. The muscles of the thigh and of the leg were found under palpation to be tense, firm, and resisting. All motion in the joint seemed to be impossible by any effort of the will of the patient. Attempts made by forced extension to straighten the limb were met by exclamations of suffering and a still further state of tension in the muscles of the extremity at once took place.

Failing to obtain satisfactory information from the examination I was permitted to make with regard to the apparent pathological conditions which were present, I stated to the mother of the patient who was present that it would be necessary to administer ether to her daughter in order to remove any resistance on her part, and to facilitate the examination required to be made to determine the nature of the abdominal growth and of the flexed knee-joint. To this proposition the patient strenuously objected. When urged to express her reasons for the refusal to be placed under the influence of ether she stated that patients who took ether "talked when they were asleep." In this attitude of belief she persisted, although informed that all statements which she might make when in a state of anethesia would be held in strict confidence by her mother, and that her medical adviser was forbidden by professional ethics from betraying any secrets divulged by patients under any conditions. After some discussion a compromise was effected, the patient agreeing "to take chloroform," under the influence of which she stated patients did not talk. The dangers incident to chloroform inhalation were fully explained, and were lightly dismissed by her when considered in connection with the other and greater dangers of "talking when asleep."

On the day following I visited the patient and placed her profoundly under the influence of ether, the medical knowledge of the patient not extending to such a degree as to render her able to recognize any difference in the character of the anesthetic agents. Fully satisfied that she would not talk while asleep under the influence of chloroform, she did not talk, and no important secrets were divulged while in a state of anesthesia under the influence of ether. When completely anesthetized the abdomen was exposed and on inspection the swelling was found to have disappeared—the most careful examination failed to discover any abnormal condition—the abdominal walls were flaccid and deep palpation could be made without showing the presence of any disease of the ovary or of associated organs. Under the relaxing influence of the anesthetic agent the limb had resumed spontaneously a straight position—by manipulation of gentlest kind it could be flexed and extended to the fullest extent—no grating sound was evoked by movements and in all respects the joint was found to be normal.

Waiting until full consciousness of the patient was accomplished, I observed that the conditions of abdominal swelling and flexure of the knee-joint returned with a somewhat abrupt effort on her part, and with a facial expression indicating that some disclosures had been unwillingly made. Two days later I visited the patient and informed her that the examination which had been made gave undoubted evidence that the conditions from which she was suffering were amenable to treatment, without the need of any surgical procedures, which I was informed had been advised by a prominent gynecologist and surgeon who had been called into consultation, and who had made an examination without the aid of an anesthetic. In accomplishing her restoration to normal health, I stated that it was absolutely necessary I should have her confidence and active cooperation, to which proposition, after a gentle suggestion that it might prove a shock and, possibly, a grief to her family to learn the exact nature of her ailments, she gave acquiescence, with the saving remark that she would regard the divulgence of the character of her illness as, in a way, a flagrant violation of professional confidence on the part of the medical adviser. To this statement I cordially assented,

and began treatment with the administration of a mild tonic, massage over the abdominal swelling and of the knee-joint, with movements of flexion and extension practised daily to revivify, as it were, the muscular structures of the limb, and restore the normal function. In a few days the patient was able to leave her bed and was carried to the porch where she sat in an easy chair with the affected limb in an elevated position on a rest, thus testifying to the fact that it was the subject of a disordered condition. Later locomotion was aided by crutches, the employment of these agents being regarded as necessary to assist the bodily movements and to avoid a too rapid return to normal methods, which might excite the suspicions of observant friends who should be disposed to regard the quick convalescence as savoring of things miraculous. In due time came carriage drives over the beautiful country roads, with restful days in the open air in shady groves and a gradual return to participation in social enjoyments.

With the end of the summer season the patient returned with her family to the city home, in all respects in normal health. On the return of the family physician from his sojourn abroad, she greeted him in the reception salon instead of in her boudoir where he expected to find her, still a subject of grave surgical affections which might demand operative interference in the near future. Calling on me promptly for an explanation of the methods employed in accomplishing results which had apparently baffled his endeavors for so long a time, I handed him from my library shelves a monograph entitled "Phantom Tumors," contributed to medical literature by a distinguished medical author. "Hysterical Joints" might well have been discussed in the same pages—conditions which, even at that period of modern surgical practice, had claimed attention and study.

The second case, illustrating results which may be designated as following methods of practice popular in the day of which we write, I shall describe briefly and without detail. A woman, unmarried, approaching forty years of age, came to me from one of the interior cities of my State for surgical advice and operative interference. With the utmost sincerity and candor she informed me that she had been subjected to several surgical operations which, as she bluntly stated, had removed all of the organs of generation, clearing out the cavity in which they were contained and leaving nothing behind but the "stumps," as she expressed it. With the information she had given I informed her that nothing more could be done by any surgical operation and advised her to return home. She then stated that she desired me to remove the "stumps" which gave her pain and which she was determined to have removed. If I would not perform the operation, she asserted vehemently, she would consult an advertising surgeon whom she knew who would do it.

Feeling that I might help this deluded person, the subject of many surgical procedures, according to her statement, I sent her to the hospital to be admitted into the surgical ward under my care, instructing the interne to make a careful record of her case, to observe her condition from day to day, to keep her rigidly in bed, and to treat her as a gravely sick patient. On inspection a cicatrix in the abdominal wall was found and digital examination disclosed the fact that the neck of the uterus had been the site of operation. No definite information could be obtained by palpation as to the condition of other organs belonging to the generative system. Her mental condition was apparently normal and physically she gave evidence of being in good health. She was resolute in her determination to have the "stumps" removed. Keeping her under observation for a week's time, in which I studied the conditions present in her case, I decided to influence her perturbed mental state if possible by performing a *quasi* operation, very simple in character, but deemed to be sufficient to accomplish the purpose. For this purpose the patient was placed upon the operating table, an anesthetic administered, and a simple scratch was made with the scalpel over the site of the cicatrix in the abdominal walls. Dressings of an elaborate character were applied, the patient returned to bed and care taken by the attention given her to impress her profoundly with the important nature of the operation which had been performed and the necessity of great care in conducting her recovery. No permission was asked to inspect the "stumps" which she had so earnestly desired to have removed. She expressed herself as greatly relieved, and at the expiration of two weeks returned home to all intents and purposes cured.

I believe the method of treatment employed in this case was not only legitimate, but in every respect justifiable. While we cannot sit in judgment on the necessity for operative interference in her case to relieve conditions the character of which we know not, we can certainly say that she became the subject of mental perversions which would have jeoparded her life, possibly, by placing her in the hands of the advertising surgeon, or sent her into the fold of the prayer-healers as an unhelped subject of scientific medicine, to swell the growing army of believers enlisted as recruits from those hostile to its progress.

The third case was not under my immediate care. Asked to assist, by the surgeon to whom the patient came for advice, I was placed in general charge, and had an opportunity to study the case which presented such interesting features as to warrant record. The patient, a woman between forty and fifty years of age, of slight physical development, with evidences of progressive emaciation, gave a history of epileptiform seizures, the aura initiating the attacks taking origin in the thumb of the right hand and passed up the arm, as she described it, until it reached her head when the seizure would occur. The convulsive movements, she stated, were limited to the side of the body on which the aura took origin and were not accompanied by mouth frothing or inversion of the thumb so far as she knew. They occurred frequently and the hand, forearm, and arm were the seats of intense pain, the suffering, which forbidding doses of morphia—½ to 1 grain in amount—did not ameliorate, but which I was able to quiet with a syringe full of cold water hypodermatically administered—being so great as to have become unendurable, and she had determined, unless relieved by surgical operation, to take her life. She insisted upon the removal of the hand in which the trouble began and the surgeon decided, without consultation so far as I know, to comply with her request.

In her ordinary garments the patient took a seat in a straight-backed chair and her body was covered by a sheet to protect her dress from being soiled by blood. She refused to be placed under the in-

fluence of an anesthetic agent, asserting that it was her desire to see how the operation was performed and, presumably, to know that it was properly done. The fore-arm being exposed, the hand was grasped by an assistant, and without any attempts at cleansing the field of operation, amputation was performed at a point midway between the elbow and wrist-joint. Throughout the entire procedure the patient did not express any sensation of pain, holding her arm rigidly firm and watching, with apparent interest, the steps of the operation. During the period of convalescence from the operation, which took place favorably, no seizures occurred and the patient returned to her home in the country quite well satisfied that the operation would effect a permanent cure.

With the subsequent history of the case I am not familiar. A dissection was made of the part removed. With the exception of a possible swelling of the median nerve and its digital branches, there was no evidence macroscopically of any morbid condition which could have caused the intense pain complained of by the patient. Unfortunately, a microscopic examination was not made of a section of the nerve, which might have given information as to the presence of possibly degenerative changes following inflammatory attacks.

I make no comments upon the methods of treatment employed in the cases I have recorded. They seem to possess interest as subjects which suggest reflection on the part of the disciple of scientific medicine to-day, to increase, if possible, the sense of responsibility which rests upon him in recognizing not only his duty to heal the body, but to so minister to the mind in such cases as it may be needed, as will correct perverted states, and maintain the faith of those who may come to him for advice and counsel, in the integrity of purpose which the practice of the science of medicine confers. In this way only it would seem possible to erect impassable barriers to stop the progress of the advancing armies of disciples of dissembling creeds, whose banners bear escutcheons with the distorted legend, *"Non omnibus sed sibi."*

THE SIGNIFICANCE AND MANAGEMENT OF CHRONIC DISCHARGING EARS.*

By ALFRED BRAUN, M.D.,

NEW YORK.

VISITING OPHTHALMOLOGIST, WASHINGTON HEIGHTS HOSPITAL; ASSISTANT AURAL AND OPHTHALMIC SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL; LECTURER IN LARYNGOLOGY, NEW YORK POLYCLINIC.

An abscess in any part of the body is regarded as a menace to the human organism, and a condition to be gotten rid of, as soon as possible, yet a chronic discharging ear, which is nothing more than a chronic abscess in the middle ear, and the adjoining bony cavities, is often regarded with complete indifference, not only by the laity, but even by many physicians. It is a common superstition among the laity, that a discharging ear should be left alone. The discharge is supposed to be the "badness" which is coming out of the child, and it is dangerous to stop it. The origin of this superstition is very evident. It is a well-known fact, that intracranial complications of ear disease are usually accompanied by a cessation or diminution of the aural discharge. This is due to blocking of drainage from the middle ear. But it is an entirely different matter to go to the seat of the trouble, and eradicate the disease.

This indifference is shared by many physcians. When their attention is called to the presence of a running ear, by the parent, they will often say that as long as it doesn't bother the child, it is best to leave it alone, as the child will probably outgrow it.

All physicians recognize the seriousness of suppuration in the nasal accessory sinuses, and nobody would hesitate to advise interference, as soon as a diagnosis of accessory sinus disease is made; yet suppuration in the middle ear is a much more serious condition, as there are many more vital and important organs in relation with the middle ear, than with the nasal accessory sinuses. Intracranial complications are much more common with middle ear disease, than with accessory sinus disease.

The roof of the middle ear is a thin plate of bone, no thicker than paper. This is all that separates the middle ear from the temporo-sphenoidal lobe of the brain. Erosion of this plate of bone results in epidural abscess, brain abscess or meningitis. The

Fig. 1.—Longitudinal section of the right temporal bone (schematic) T, Tympanic cavity; AD, aditus; AN, antrum; CR, cranial cavity; F, facial nerve; C, internal carotid artery; J, jugular bulb; S, lateral sinus.

mastoid cells are separated by a thin plate of bone from the lateral sinus and cerebellum. Erosion of this plate of bone may result in perisinus abscess, sinus thrombosis with pyemia, cerebellar abscess, or meningitis. The oval window leads into the vestibule of the internal ear, and the round window, into the cochlea. Disease spreading through either of these two openings, or through the horizontal semicircular canal, which lies exposed in the aditus, leads to suppuration of the labyrinth, with complete deafness, and a possible extension of the disease through the internal auditory meatus, to the posterior fossa of the skull, with meningitis or cerebellar abscess.

Under the posterior portion of the floor of the middle ear, lies the jugular bulb, extension to which, may cause thrombosis of the bulb, with pyemia. Below and internal to the tympanic orifice of the Eustachian tube, lies the internal carotid artery, erosion of which, causes uncontrollable hemorrhage.

*Read at a meeting of the Bronx Medical Society, March 13, 1912.

Passing along the inner and posterior walls of the middle ear, is the facial nerve, exposure of which, causes paralysis of one side of the face.

In the face of all these possible dangers, it is perfectly evident that no case of middle ear suppuration should be allowed to go on unchecked.

What are the factors which tend to prolong an acute middle ear suppuration, and transform it into the chronic form? One of the most important factors, is the presence of hypertrophied tonsils and adenoids. This lymphoid tissue contains septic material, which gives rise to repeated infection of the middle ear, through the Eustachian tube. The child is scarcely over one attack, when there is a second infection. After a time, the mucous membrane in the middle ear is so changed, that a condition of chronic suppuration is set up. Another way in which adenoids act, to prolong the middle ear suppuration, is by interfering with proper drainage of the middle ear through the Eustachian tube.

Another factor in prolonging acute suppuration in the middle ear, is an extreme intensity of the infection, causing a destruction of the mucosa in certain areas of the middle ear, with a resultant necrosis of the underlying bone. This is especially apt to occur in the scarlatinal and diphtheritic infections.

A third factor, is the general condition of the patient. In an anemic, poorly-nourished child, with poor recuperative powers, the suppuration is very apt to become chronic. Syphilis or tuberculosis is sometimes at the bottom of a persistent suppuration.

A fourth factor is the extension of the suppurative process into the antrum and mastoid cells. It is claimed by many otologists that every middle-ear suppuration extends to the mastoid antrum. This may be so, but in a large proportion of cases the communication between the antrum and middle ear is so free that the pus in the antrum can drain freely through the perforation in the drum membrane. Where the passageway between the antrum and middle ear is very narrow, suppuration is apt to be prolonged.

Finally, the anatomical conditions within the middle ear have an important bearing on the prolongation of a suppurative process. In some cases of middle-ear suppuration, the disease expends most of its force in the upper portion of the middle ear, or epitympanic space. The communication between the epitympanic space and the middle ear proper is narrowed down very considerably by the presence of the major ossicles, the malleus and incus, and their ligaments. In addition to this there are, in some cases, folds of mucous membrane stretched between the ligaments and the walls of the attic, so that the epitympanic space is almost completely shut off from the middle ear proper. When the suppuration becomes localized here, the drainage is so poor that the condition is very apt to become chronic. This condition is recognized by the fact that the perforation is situated in Shrapnell's membrane, or by necrosis in the upper part of the annulus tympanicus, whereas the membrana tensa is normal.

What, then, are we to do when we are brought face to face with a case of chronic suppuration in the middle ear? In the first place, I think that a chronic running ear should be treated by the otologist only. I think that the general practitioner, if he learns how to use an ear speculum and a head-mirror, can do a paracentesis, and treat the simple cases of acute middle-ear suppuration; but in chronic middle-ear suppuration, the pathological conditions are so varied, and the possibility of latent intracranial complications is so great, that only the trained otologist is at all fitted to cope with the situation. And in many cases even the most skilful otologist fails to bring about the desired result.

The diagnosis of chronic suppuration of the middle ear is simple enough. The patient, or the parent of the patient, makes the diagnosis. But here, a word of warning. The statement of the patient will often mislead you in regard to the duration of the suppuration. Sometimes the discharge is so slight in amount that it does not flow out of the canal, and the patient is not aware of the suppuraion. If, in the course of the suppuration, the pus increases in amount, the patient will tell you that his suppuration has lasted only a few days, whereas this is only an acute exacerbation of a chronic condition. The diagnosis as to the chronicity of the condition must be made by the appearance of the middle ear and the character of the discharge. In chronic cases

Fig. 2—Horizontal section of the left temporal bone (schematic): T, tympanic cavity; A, antrum; F, facial nerve; I, internal auditory meatus; C, internal carotid artery; S, lateral sinus; CO, cochlea; SS, superior semicircular canal; ES, external semicircular canal; PS, posterior semicircular canal.

the discharge is apt to be foul smelling, the membrana tympani is not acutely inflamed or swollen, there may be granulations in the middle ear, and necrotic bone may be seen or felt with a probe. The presence of cholesteatoma is a positive indication of a chronic middle-ear suppuration.

The cases of persistent chronic running ears are not the only serious ones. Just as serious, and often more so, are the cases of recurrent middle-ear suppuration. These are the cases where the patient has an attack of middle-ear suppuration every few months, or even every year or two. In the majority of cases, these are not individual acute attacks, but merely exacerbations of a chronic condition. In the intervals there are no subjective symptoms, but the disease-process is progressing all the time. Experience teaches us that it is in this type of cases that we are especially apt to get intracranial complications.

Having made our diagnosis of chronic suppurative inflammation of the middle ear, what is our

method of procedure? We must first, if possible, determine what is at the bottom of the continued suppuration. If there are hypertrophied tonsils and adenoids present, these should be removed. If the patient is poorly nourished and anemic, he should be built up and given tonic treatment. If tuberculosis or syphilis is present, the treatment suitable to these conditions should be instituted.

If, after having eliminated every possible underlying cause, the suppuration still persists, what are we to do? We can divide the cases of chronic suppuration into two classes, as far as the pathology, dangers, and treatment are concerned. In the first class, the disease is confined entirely to the mucous membrane lining the middle ear. This type may run on for many years, without extending any further, with no other symptom except the discharge, which is mucopurulent, or even purely mucous in character, and has no offensive odor. This class of cases can often be cured by simply keeping the middle ear clean. One of the best ways of cleansing such an ear is by dropping a few drops of peroxide of hydrogen into the middle ear, and after allowing it to bubble up for a few minutes, irrigating the ear with warm water. In the cases in which the attic is largely shut off from the middle ear proper, irrigation of the attic by means of a small cannula inserted into the attic through the perforation in the drum membrane may cure. I have seen cases of 15 or 20 years' duration dry up in a few weeks under such simple treatment.

In some of this type of cases the suppuration is undoubtedly kept up by repeated reinfections from the nasopharynx, through the Eustachian tube. These can be cured by means of the Yankauer operation. This consists in curetting the mucous membrane from the isthmus of the Eustachian tube by means of a specially constructed curette with a curved shank, which is introduced through the perforation in the drum membrane. This curettage is followed by a cicatricial closure of the tube at its isthmus, thus preventing any further reinfection of the middle ear from the nasopharynx.

The second class of cases consists of those in which, in addition to involvement of the mucous membrane, there is necrosis of the bony contents or walls of the middle ear and adjacent cavities. These are the cases which cause serious symptoms and often result in death. In the vast majority of these cases the disease is not confined to the middle-ear cavity, but involves also the mastoid antrum. In these cases the middle ear and external auditory canal simply serve as a means of exit for pus which is being formed in the mastoid antrum and cells, or even within the cranial cavity. Consequently it is foolish to hope to cure these cases by means of local treatment directed to the middle ear.

These cases of chronic middle-ear suppuration with necrosis are recognized by the appearance of the middle ear and the character of the discharge. The discharge usually has a very offensive odor. It may be thick and creamy, but is usually thin and brownish. It may be bloody, when there are granulations present. The perforation in the drum membrane is apt to be marginally situated, especially at the upper posterior margin, near the antrum, and the bony margin may be necrotic. The presence of granulation tissue in the middle ear or canal is usually indicative of necrotic bone. The necrotic bone may be felt by introducing a probe through the perforation into the middle ear. The presence of cholesteatoma always indicates extensive destruction in the middle ear and adjacent cavities. Cholesteatoma consists of a mass which lies in the middle ear and antrum, consisting of desquamated epithelial cells and cholesterin. It is recognized by its pearly white color and its foul odor. The odor is so characteristic that when once smelt, it is never forgotten. By mechanical pressure the cholesteatoma causes an erosion of the bony walls, and in this way the dura may be laid bare. It also forms a very excellent culture medium for bacteria.

In addition to these objective signs in the middle ear there are certain subjective symptoms which indicate a necrotic process in the middle ear and its adjacent cavities. There are periodic attacks of pain in the ear and side of the head; or the pain may be more or less constant. There may be headache. Vertigo, vomiting and nystagmus, with complete deafness, indicate that the disease has extended to the internal ear. Facial paralysis indicates necrosis of the bony covering of the facial nerve as it passes through the walls of the middle ear. There may be tenderness and swelling behind the ear, indicating the presence of mastoiditis. There may be symptoms of sinus thrombosis, brain abscess, or meningitis.

Ninety per cent. of cases of brain abscess are caused by suppuration in the middle ear. Practically all of the cases of thrombosis of the lateral sinus are caused by ear disease. A large proportion of the cases of purulent leptomeningitis is caused by ear disease.

The cases of middle-ear disease with necrosis cannot be relieved except by operative intervention. The operative intervention consists of one of several procedures: either ossiculectomy, the Heath operation, or the radical mastoid, of which there are two types, the Stacke and the Schwartze-Stacke. Ossiculectomy is efficacious in only a small proportion of cases. There are two classes of cases which are benefited by this procedure. First, the cases where the necrosis is limited to the ossicles. But we can never be sure that the necrosis has not extended to the walls of the middle ear and the adjacent cavities. Secondly, the cases where the attic is shut off from the middle ear proper, as the result of adhesions and granulations about the major ossicles, thus resulting in obstruction to drainage.

Ossiculectomy consists in the removal of the malleus and incus along with what is left of the drum membrane. It is not a perfectly harmless procedure, as some of the granulations in the middle ear may spring from the dura, and the removal of the granulations may start up an infective process in the meninges. In attempting to remove the incus, the stapes may be torn out of the oval window, and an infective labyrinthitis set up. The facial nerve may be injured, and a facial paralysis result.

The so-called "Heath" operation consists in opening up the mastoid antrum, and taking down the posterior canal wall, up to the annulus tympanicus, not disturbing the contents of the middle ear. The purpose of the operation is to conserve the hearing, if possible. It is based on the theory that a large proportion of cases of chronic suppurative middle-ear disease is kept up by suppuration in the antrum. But the surgical principle of the operation is bad. Good surgery demands the complete removal of all diseased tissues, whereas this operation deliberately leaves necrotic bone in the middle ear. The cases which get well, as a result of this operation, are either cases which would have gotten well as the

result of conservative intratympanic treatment or cases which would have gotten well with a simple mastoid operation.

After all, the vast majority of cases of chronic suppurative middle-ear disease with bone necrosis will not get well except with a radical mastoid operation. The two forms of radical operation are the Stacke and the Schwartze-Stacke operations. In the Stacke operation an incision is made behind the ear, as for a simple mastoid operation. The antrum is opened, the posterior canal wall is taken down, as far as the facial nerve will allow, thus making one cavity out of the middle ear, external auditory canal, and antrum. A portion of the roof, anterior wall, and floor of the canal is removed, so as to obliterate all recesses in the middle ear. The ossicles and all necrotic bone are removed. The posterior wound is then sewed up, and a skin-flap made in the meatus, and the entire bone cavity allowed to epidermatize. The Schwartze-Stacke operation consists in the removal of the mastoid cells, in addition to the above operation, and is indicated in those cases where the mastoid cells are diseased.

When you broach the subject of a radical operation to your patient, he will naturally ask what results you expect to obtain from the operation, and what are the dangers thereof. There are several points to consider. First, is the operation necessary, in order to save life? Second, will it stop the discharge? Third, will it improve or restore the hearing? Fourth, will it prevent the possibility of future intracranial complications? Fifth, what are the dangers of the operation?

In regard to the first point, there are several classes of cases in which the operation is a life-saving measure. These are the cases where chronic middle-ear suppuration is complicated by a mastoiditis, brain abscess, epidural abscess, meningitis, or disease of the labyrinth. A facial paralysis coming on in the course of a chronic middle-ear suppuration is an absolute indication for operation, as this is usually one of the accompaniments of labyrinthine disease.

In regard to the second point, as to whether it will stop the discharge, we must answer that it does not do so in all cases. But in the majority of cases persistence of discharge is due to an improperly performed operation. The operation must be so performed that all recesses and crevices in the middle ear are obliterated, so that there is no place for secretion to stagnate. With a complete, correctly performed radical operation, 90 per cent. of the cases should dry up. The remaining 10 per cent., even though they are not thoroughly cured, are usually so much improved that the patient is well satisfied, and does not mind the slight amount of discharge which persists.

In regard to the third point, as to whether it will improve the hearing, we cannot say definitely beforehand. In many cases the hearing is not changed much by the operation. Where the hearing has been very good before the operation, it is usually made worse by the operation. On the other hand, where the hearing has been very poor, and where there is no labyrinthine disease, the hearing is usually improved by the operation.

As to whether it will prevent future complications, we can say that they are much more likely to be prevented by this method than in any other way that we know of.

Finally, in regard to the dangers of the operation. In the hands of a skilled otologist, who is thoroughly conversant with the anatomy of the region and who has done many of these operations, the dangers are practically nil. Facial paralysis, following the operation, is usually due to faulty technique. The stapes may be torn out of the oval window during the operation, setting up a purulent labyrinthitis, but this can be avoided by a reasonable amount of care. Injury to the dura, jugular bulb, carotid artery, or labyrinth need not occur in a carefully performed operation. Occasionally, even after a perfect operation, symptoms of brain abscess or meningitis set in, followed by death. But these are cases in which the intracranial condition was already present in a latent state, before the operation, and was simply fanned into activity by the traumatism incident to the operation.

616 Madison Avenue.

HOW THE DEPARTMENT OF AGRICULTURE TREATS THE LOCO DISEASE; A LESSON IN COMPARATIVE PSYCHIATRY.

By BAYARD HOLMES, M.D.,

CHICAGO, ILL.

For centuries there have been abundant story and tradition among the Mexicans of the use of the loco weed by the love-lorn and the criminal; but the contact of the American and the Mexican civilization in the middle of the last century did not bring this dire plant into English fiction until 1882. In the first volume of *Scribner's Monthly* (p. 75) Thomas A. Janvier referred to this Mexican tradition and used it in a popular story, but his description of the plant was so incorrect that it is plain he used a stramonium for his literary model.

As cattle raising on the plains began to command national economic attention gossip among rangers furnished many yarns of "locoed" horses and other animals. These half-credited stories at last became the basis of irrefutable economic statistics and the various local governments in the semiarid region undertook to exterminate the loco weed.

The Department of Agriculture in 1873 published a short account of the loco disease in which O. B. Ormsby of Bakersfield, Cal., is quoted, and this early description is classical; he describes the effect of the plant as follows: "It prevails quite abundantly over an extent of 150 square miles in this valley and is found in other valleys of the State and also in Arizona. This year the army worm and a minute insect which destroys the seed have killed a good deal of it, but if not molested it will flourish to as great an extent as ever. I think very few if any animals eat the loco at first from choice, but as it resists the draught until other feed is scarce they are at first starved to it, and after eating it a short time they appear to prefer it to anything else. Cows are poisoned by it as well as horses, but it takes more to affect them. It is also said to poison sheep. As I have seen its action on the horse, the first symptom of the poison apparently is hallucination. When led or ridden up to some little obstruction, such as a bar or rail lying in the road, the animal stops short and if urged leaps as though it were four feet high. In the next stage he is seized with fits of mania in which he is quite uncontrollable and sometimes dangerous. He rears, sometimes even falling backward; runs or gives several successive leaps forward and generally falls down. His eyes are rolled up until only the whites can be seen. They are strongly injected. He sees nothing and is apt to leap against a wall or

a man. Anything which excites him appears to induce the fits, which I think are more apt to occur crossing water than anywhere else, and the animal sometimes falls so exhausted as to drown in water not over two feet deep. He loses flesh from the first and sometimes presents the appearance of a walking skeleton. In the next and last stage he only goes from loco to water and back. His gait is feeble and uncertain and his eyes are sunken and have a flat, glassy look. His coat is rough and lusterless. In general the animal appears to perish from starvation and constant excitement of the nervous system, or sometimes appears to suffer acute pain, causing him to expend his strength in running wildly from place to place, pawing and rolling until he falls and dies in a few minutes."

This paper of George Vasey was distributed widely as a Farmers' Bulletin, but no mention of the subject appears in the medical literature for more than ten years.

The first notice of the condition in the psychiatric literature, so far as I have read, was made by Dr. Henry M. Hurd to the committee on new remedies of the Association of Superintendents and published in the *Journal of Insanity*, vol. XLII, October, 1885, p. 176. His description is graphic and valuable.

"Ranchmen say that no animal will eat the 'loco plant' unless driven to it by great hunger. After eating it for several days they begin to crave it, and soon prefer it to all other forage. It has been noticed that a horse who has become accustomed to eating loco will refuse all good food and wander for miles in search of the plant. It seems to produce a sort of intoxication at first, and afterwards hallucinations of vision. It is impossible to lead the animal through a gate or into a barn. He walks mincingly, magnifies the size of trifling objects in his path, shies without any cause, and becomes unmanageable. He seems apprehensive of danger and can neither be coaxed nor driven. His gait becomes unsteady and he is manifestly ataxic. He pays little attention to his driver and stands with drooping head and seems indifferent. It is difficult to get him started and equally difficult to stop him. He becomes headstrong, indifferent to the bit, and extremely difficult to drive. If driven into the water or near water, he rushes headlong into the stream and often lies down and refuses to rise. He refuses all food except loco, and rapidly emaciating dies of exhaustion. There is often great cutaneous hyperesthesia, especially in the region of the neck and face. If the horse is struck ever so lightly under the jaw with the flat of the hand, he struggles violently and frequently throws himself backward upon his head. All power of reasoning is gone and he seems utterly unable to control his morbid impulses. If the horse be removed from the plant at an early stage of his disorders and started into eating other food, the disease may be arrested, but complete recovery is impossible. The horse is ruined. Cattle are affected much the same way. They lose all ability to care for themselves and wander about in a daze, confused state, and die from exhaustion. They are frequently tormented by a persistent thirst and instinctively seek water, which they lie down in. In many instances they drown in a few inches of water because too indifferent or too stupid to make any effort to get out of it."

In Bulletin 45 of the Montana Agricultural Experiment Station, June, 1903, J. W. Blankenship shows that the cost of loco disease in Montana was not far from $100,000 per year or 0.3 per cent. of the total valuation, $44,000,000. He discusses the subject fully and gives a vivid description of the symptoms of the disease. There are many interesting points in this description of the disease at its northern limit.

"The loco is a slow poison and appears to affect primarily the nervous system so that animals addicted to the habit become stupid, wander from herd to herd, step high, their eyes are glassy, their front teeth grow long and become loose, their coat becomes shaggy, and they seek the loco weed and will eat nothing else if it can be obtained. They not only eat the plant itself but dig for the roots with their hoofs. They appear to have false ideas of form, size, and distance, and horses, particularly when hot or exhausted, are apt to become frantic. Hence the term 'loco' or crazy, has been affixed to the disease. Moreover, the effects are usually lasting and no remedy has been found. Horses are permanently injured as their crazy spells disqualify them for hard work. Few cases of recovery have been noted."

The early botanists found that several plants produced the loco and the pharmaceutical chemists sought without success for some alkaloid similar to those of its cousins, the Jamaica dogwood and the Calabar bean. The *Astragalus* is the principal source of the disease. It is a leguminous plant that roots deep in the ground and retains its greenness long after most plants have dried up.

The plant is not poisonous until it has been eaten in considerable quantities for two or three months.

In 1893 N. S. Mayo tried the plant on animals and even ate it himself with no bad result; but when he went into the ranges and saw the sick animals he changed his mind and he decided that the loco was a real disease. His description is full, careful, and scientific.

Dr. A. J. Givins in 1893 tried the tincture of *A. molussimus* on three insane persons with no effect either for better or worse.

McCullough, in describing the condition in 1892, mentions all the symptoms that others had emphasized and notes the appearance of exostosis of the frontal bone, and warns buyers to feel of those parts when buying horses from locoed regions. This is an early symptom.

Marshall made his studies of the loco disease mostly on sheep and considered very largely the terminal condition. He failed to discover any adequate cause in the loco weed and found the sheep toward the end of life infested with all sorts of parasites.

These observations are very interesting as compared with the ordinary observations in institutions for the insane where the secondary diseases are often described as a part of the primary condition which led to the mental aberration.

In 1898 the Department of Agriculture collected statistics of the loss by the loco disease. Colorado had already expended $425,000 during the preceding nine years in attempts to eradicate the weed. In Montana the loss was irregular. In one range 300 out of 2,000 cattle died of loco in one season, but later the weed was exterminated in May and June and no more animals were sick. In 1905 the Agricultural Department, in cooperation with the State of Colorado, began a systematic investigation of the disease.

The results of this investigation, which covered more than three years, are published by C. Dwight Marsh (Bureau of Animal Industry, Bulletin No. 112) and by Albert C. Crawford (Bureau of Plant Industry, Bulletin No. 129). These two contributions give a clear perspective of the subject.

Several plants produce the disease and all hoofed animals are susceptible at all ages. The watery, alcoholic, and other extracts have not proved poisonous. Crawford found that the ash of the loco plants contained barium salts and that these salts were poisonous. Marsh, in his experiments, found Fowler's solution therapeutically valuable in horses, but strychnine more useful in cattle. In spite of the unfavorable prognosis in this disease, animals gained weight and recovered when well fed and thoroughly dosed with arsenic or strychnine.

In the State of Illinois with a gross income to the treasury from all sources of a little more than $10,000,000 a year, 40 per cent. or more is expended in the care of the insane and other wards not criminal. Yet the State appropriated only $11,800 a year for the investigation of the causes of insanity.

The number of the wards in the several institutions is about 19,000. If this condition of custody is expensive, their retention in the ranks of useful citizens would be a greater public gain. Not all the insane are committed. The death rate of the insane is very high. The 19,000 insane in custody are but a residue of the 5,000 or more who become insane every year.

To rescue the 0.3 per cent. of the animals locoed by eating the weed on the arid plains of Colorado and Montana, the Department of Agriculture spent several years in expensive research and has at last made commendable and rational progress.

If the work of Crawford is proved by subsequent experiments to be reliable the loco is a disease related to beriberi, to milk sickness, and to scurvy. It is in the category of toxemias not far from lead poisoning. If the salts of barium in such small quantities are potentialized by the biochemistry of the *Astragalus*, then what new toxemia may we not find with the multitude of inimical resources of nature?

With a certain outgo for a custody of meager charity of 40 per cent. of the total receipts of the State Treasury a paltry $12,000 a year for an Institute of Research into the cause, cure, and prevention of diseases that destroy one out of every 500 citizens is extravagant parsimony.

The Psychopathic Institute should be a part of the University. It should be liberally supported by a rate proportional to the life, largess, and happiness at stake. It should be looked to for a solution of the problems of the insanities as we looked to the Yellow Fever Commission.

Our precedents are numerous. As the result of research, suppuration, erysipelas, puerperal fever, and hospital gangrene are historical afflictions, surgery is possible, and the capacity of our hospitals and their usefulness are multiplied. As a result of research hydrophobia and lockjaw are robbed of their terrors. As the result of research tuberculosis, the great white plague, is routed and another generation will see it on the run. As a result of research, cholera, the plague, and yellow fever will never again blockade half the ports of commerce and stampede the frenzied population of States and cities. As a result of research the armies of the world no longer lose more by disease than by the enemies' weapons, nor need the great labors of civilization be stayed by typhoid fever, malaria, the hookworm, or disease-bearing mosquitoes. And by the same rational methods of research, the insanities will be made clear, their sources discovered, and the terrible monuments to our helpless ignorance will disappear from the face of civilized States. With such a history why these millions for custody and not a mite for research?

The bibliography of loco disease has been written by the following authors:

Sayer, L. E.: Bibliography of the loco weed. Trans. Kansas Academy of Sciences, vol. XIX, p. 194-197 (1903-1904).

Marsh, C. D.: The loco weed disease of the plains. Bureau of Animal Industry, Bulletin 112, 1909.

Crawford, A. G.: Barium as a cause of loco disease. Bureau of Plant Industry, Bulletin 129, 1908.

THE DIFFERENTIAL DIAGNOSIS OF ALCOHOLIC COMA.

By HUBERT V. GUILE, B.S., M.D.

NEW YORK.

ADJUNCT ASSISTANT VISITING PHYSICIAN, BELLEVUE HOSPITAL.

The diagnosis of alcoholic coma is perhaps one of the most difficult and obscure problems that the clinician is called upon to elucidate. This is chiefly due to the fact that the condition presents so few characteristic symptoms and no pathognomonic signs upon which any reliance may be placed. In addition, there are unhappily many other types of coma in which the same statement will hold true. If we could only be sure that we were dealing with but one clinical entity our position would not be so perilous; but frequently there is present some other complicating condition, which for the time being is obscured by the associated alcoholism. For it is unfortunate but true that among the more ignorant classes, when illness befalls them, their first recourse is to alcohol, which is held in high repute as a panacea for all ailments. Then again, those under the influence of alcohol are subjected to a rare and varied assortment of violence. While at times it might seem as if there were a special providence that stands guardian for the intoxicated, yet we know that alcohol cannot increase the tensile strength of bone or lessen the chances of intra-abdominal injury. In addition it must be borne in mind that the vasomotor depression usually present in the acutely alcoholic prevents to a considerable degree the evidences of shock that would ordinarily be present in a sober individual subjected to the same amount of trauma. This fact alone might readily mislead one in underestimating the seriousness of a patient's condition.

These are but a few of the difficulties that present themselves in the diagnosis of alcoholic coma. To be sure, the condition can frequently be diagnosed with some degree of certainty, yet it is well not to believe too firmly that such is the case, lest one's confidence be rudely shaken. It is far safer to approach the case with an air of scepticism, resorting rather to the process of exclusion at the expense perhaps of one's reputation for positiveness.

In alcoholic coma the degree of unconsciousness varies considerably. Many can be aroused from their stupor by simple pressure upon the supra-orbital nerve, by pricking the internasal septum

with a pin, or by briskly slapping the face. Frequently a whiff of ammonia will elicit a vigorous response. While it is generally accepted that one in alcoholic coma can be aroused in contradistinction to other types of coma, nevertheless there are many cases in which the intoxication is so profound that all the superficial and deep reflexes are abolished and no response to external stimuli can be obtained. There is nothing characteristic about the respiration. It is deep and regular, slightly accelerated, occasionally stertorous, rarely Cheyne-Stokes in type. The pulse is usually of good size, regular in its force and frequency. The rate is often increased and the tension is invariably low. At times it may show dicrotism. The temperature is seldom above normal unless of course some complication is present. More often it is subnormal, especially after exposure. In fact, a temperature between 85 and 95° F. is almost pathognomonic of alcoholism, provided starvation and wasting diseases be excluded. In these cases it is often agonal or preagonal in time.

The face is flushed, often cyanosed and frequently shows the stigmata of chronic alcoholism. The pupils are moderately dilated and react to light. As a rule they will dilate still further upon slapping the face or pinching the skin of the side of the neck. On rare occasions the pupils may be pinpoint as in morphine poisoning. It is well to bear in mind in this connection that inequality of the pupils often occurs in people who are normal in all other respects. Also chronic alcoholics when sober frequently have unequal and irregular pupils that react quite sluggishly to light and accommodation. This condition is also present in cerebral arteriosclerosis and cerebral syphilis. And of course there is no reason why a tabetic or a paretic should be immune to alcoholic coma. Therefore little or no reliance can be placed on the condition of the pupils.

The alcoholic odor of the breath is, needless to say, of no value. It is dangerously misleading. However, its absence speaks fairly positively against alcoholic coma, especially in those cases that have been in coma for only a short period of time. Gastric lavage will usually show alcohol in excessive amounts together with a large quantity of poorly digested food. The stomach having been washed out, the patient should begin to regain consciousness in the course of the next few hours. Should this not occur, it would be well to suspect that there may be some complicating condition present; or that the case is not alcoholic coma at all. While it is not common, patients do, however, die from acute alcohol poisoning, notably after the ingestion of wood alcohol. However, such a conclusion should not be reached until every other possibility has been considered and eliminated.

In every case of suspected alcoholic coma a most thorough and painstaking examination should be made. The body must be minutely searched for signs of trauma. The skull should be palpated for evidences of depressed fracture and the scalp inspected for signs of hematoma. Subcutaneous emphysema, especially about the mastoid and frontal sinuses, is of the utmost importance in differential diagnosis. The aural, nasal, and buccal cavities should be examined for blood. It is not enough to determine the presence of hemorrhage, but the source if possible must be found. The leakage of cerebrospinal fluid or the escape of brain substance is of course pathognomoic of fracture of the skull. Ecchymosis anywhere about the head should be regarded with grave suspicion. Frequently it will mean nothing. When it occurs on the forehead, beneath the eyes or conjunctivæ, or over the mastoid cells, especially if the overlying skin is intact, it is particularly significant. Very often ecchymosis comes on several days after the time of injury. So that it is advisable that the above sites of election should be examined two or three times in the course of twenty-four hours. The patient should be catheterized as soon as possible and the urine examined. The blood pressure should be determined hourly and the eyegrounds examined. These when normal will speak in favor of alcoholic coma.

Lumbar puncture, in recent years, has ceased to be regarded as a serious procedure; and the information gained from examination of the cerebrospinal fluid is often so valuable that it is quite justifiable to tap the cord in all cases of coma. The following findings all speak against alcoholic coma: (1) An incranial pressure above 150 mm of water. (2) A turbid fluid. The presence of fibrin flakes. Coagulation or web formation on standing. (3) An increase in the cellular content above five or ten cells per mm. (4) An increase in the globulin content. (5) A negative reaction to Fehling's solution. (6) The presence of bacteria in smear or culture. (7) A positive Wassermann, Nonne Apelt or Neguchi reaction.

The nurse should be instructed to watch the patient constantly for convulsions. These may be focal, quite brief and transitory. Unless the closest watch is kept, these may occur unbeknown to anyone and thus a most valuable and life-saving clue be lost. The patient's clothes and property should be carefully searched for any evidence that might help to throw light upon the nature of his condition. Most important of all, no pains should be spared in endeavoring to get in communication with relatives or friends of the patient. If possible eye witnesses of the onset of coma should be sought, in order that some history of the case may be obtained. If we are successful, the nature of the trauma, if there be any, and the sequence of events should be carefully inquired into, lest the cause be taken for the effect or vice versa.

Perhaps confusion in diagnosis will occur most often in cases of cerebral hemorrhage, for it is remarkable how many attacks of apoplexy seem to be precipitated by excessive indulgence in alcohol. In the majority of cases the condition will not be difficult to differentiate. For fully 70 per cent. to 80 per cent. of all cases will show paresis or paralysis of some sort. Mistakes among these will be chiefly due to carelessness. However it is among the remaining 20 per cent. to 30 per cent. that errors are prone to occur. These will show no focal symptoms. The hemorrhage as a rule is very extensive and is often of the intraventricular type. The degree of unconsciousness is in no way to be distinguished from the more severe types of alcoholic coma. In these cases it will be helpful to remember that the vast majority of apoplexies occur between the ages of forty and sixty, and over one-half show cardiac hypertrophy and the other evidences of chronic interstitial nephritis. In the differential diagnosis of this condition the history obtained from friends is often invaluable; particularly if they have seen the patient from the beginning of his acute illness. For apoplectic coma comes on far more suddenly than does alcoholic stupor. In addi-

tion many of these cases may have shown transitory signs of paralysis; for about 50 per cent. of intraventricular hemorrhages are secondary to hemorrhage into the internal capsule. Such cases after the onset may show slight improvement during the subsequent few hours. Then the patient will suddenly lapse into profound stupor. His respirations become loud and stertorous. The veins of the neck are distended, the face and extremities markedly cyanosed. Not infrequently the skin will be bathed in profuse perspiration. The limbs may be absolutely flaccid or completely rigid. In either event there is rarely any evidence of paralysis. Such a picture as this, when seen for the first time, might readily be mistaken for alcoholic coma. However, any of the following signs, if present, should make one promptly abandon the diagnosis of alcoholism and suspect the possibility of some intracranial mischief. (1) A slow, full, high tension pulse is especially significant if it can be shown that the tension is increasing while the respirations are becoming progressively slower. (2) A rapidly rising temperature without any apparent reason, taken in conjunction with coma and a slow high tension pulse, is quite suggestive. (3) A Kernig, Babinski, or Gordon reflex will rule out alcoholic coma, as will also the presence of true ankle clonus or a unilateral loss of the superficial reflexes. (4) The eyegrounds may show recent retinal hemorrhages, a slight blurring of the disc, together with a moderate engorgement and tortuosity of the veins. The beaded appearance of the vessels and the broadening of the central light streak of the arteries are good evidence of the degenerative changes of the circulatory system elsewhere in the body. (5) Lumbar puncture may show blood tinge fluid. However it must be remembered that occasionally blood is obtained from lumbar puncture in normal cases owing to perforation of the venous plexuses that surround the spinal cord. In these cases we obtain pure venous blood, a condition that does not occur in intracranial hemorrhage. Frequently if the needle be pushed further inwards, clear spinal fluid will be obtained. (6) Coma associated with glycosuria with no diacetic acid or acetone in the urine is suggestive of intracranial injury. In these cases the copper reduction is not quite as complete as is the case in diabetes.

Uremia is readily mistaken for alcoholic coma, especially in those cases in which the urine shows nothing characteristic and in which the amount of cardiac hypertrophy can be accounted for by hard work and alcoholism. To be sure anemia, edema, associated with hypertension, suppression or reduction of the urine output, together with albuminuric retinitis, when present, are all in favor of the diagnosis of uremia, but these signs are by no means constant. What is more confusing still is the fact that most alcoholics have to a greater or lesser degree some chronic interstitial nephritis to which frequently there has been added an acute exacerbation caused by their recent excesses. So that there will be cases that are indistinguishable from alcoholic coma aside from the fact that the latter condition tends to become progressively better while uremia is, of course, far more likely to terminate fatally. The recent work done with the phenolsulphonephthalein test in the estimation of renal function has undoubtedly proved of the utmost value in the diagnosis of uremic coma. For many of the grave cases of uremia show a phthalein elimination ranging from zero to a faint trace within two hours.

The differential diagnosis of diabetic coma rests practically upon the sweet, fruity odor of the breath, and the presence of sugar in the urine associated with acetone bodies. In these cases the history will often prove of the utmost importance in the absence of the urinary examination; for it is very rare for diabetic coma to develop in a patient who has never had treatment for his glycosuria at some time previously.

Epileptic convulsions followed by profound stupor are frequently precipitated by the excessive intake of alcohol. In these cases a careful search of the clothing is often of value; for many epileptics carry cards stating that they are subject to fits. Also the finding of bromides is quite suggestive. Numerous scars about the head and old lacerations of the tongue coupled with the fact that epileptics frequently show the stigmata of degeneracy are all of diagnostic value. While in many cases there will be some doubt at first as to the diagnosis of the condition, one will not remain long uninformed; for epileptics either promptly regain consciousness, pass into postepileptic excitement or confusion, or develop the status epilepticus.

The possibility of narcotic poisoning must ever be borne in mind. Of the narcotics morphine and chloral are the most frequent etiological factors. The former is distinguished, of course, by the pinpoint pupils and the marked slowing of the respiration, coupled with the fact that the patient can be aroused to some slight extent in all cases save the most serious. Chloral poisoning is not as common nor is it as easily identified. The condition resembles the third stage of ether narcosis except that the face is usually white and livid, and the skin is bathed in cold perspiration. The pupils at first are moderately contracted; later they are dilated. The reflexes are lost comparatively early. The picture resembles alcoholic coma in many respects, and this is not to be wondered at when we consider how closely the two drugs are allied, both in their chemical derivation and in their physiological action. Not infrequently we will find narcosis may be due to the combined action of chloral and alcohol; for the peculiar merit of this mixture is well known to the criminal fraternity.

In every case of apparent alcoholic coma that does not regain consciousness, the possibility of pachymeningitis hemorrhagica interna should be borne in mind. The condition is so often found at autopsy that it forms a strong contrast to the infrequency with which the diagnosis is made clinically. There are no symptoms that are characteristic of the disease. Persistent headache occurring in a chronic alcoholic without any apparent reason or following a severe head injury associated with periodical and transitory attacks of paralysis, cortical in type, is suggestive of pachymeningitis hemorrhagica interna. To be sure, these are present in uremia and in cerebral syphilis. However, in most cases the former can be diagnosed by the attendant symptoms of nephritis and the latter suspected by the presence of a positive Wassermann reaction and the other evidences of insufficiently treated lues. In regard to the attacks of coma occurring in pachymeningitis there are no signs that may not be present in cerebral hemorrhage save, if one recognizes the pathology of pachymeningitis, it can be readily seen it is impossible for blood to be found in the spinal cord fluid. In short, if one is to make the diagnosis at all it will be based upon the history of the case prior to the onset of coma.

Little difficulty should be experienced in recognizing hysteria simulating alcoholic coma. The peculiar insincerity of the clinical picture, the tendency to pose, the rolling of the eyes, the contrast between the pharyngeal, conjunctival, and cutaneous anesthesia and the prompt reaction usually obtained from a whiff of ammonia applied to the nose are inconsistent and quite characteristic of the condition.

Occasionally in alcoholics, attacks of unconsciousness are associated with the Stokes-Adams syndrome. The extremely slow radial pulse, and the auricular dissociation as evinced by the pulsation of the jugular bulb, should suggest the possibility of cerebral anemia due to heart block. The diagnosis is, of course, readily confirmed by a polygraph tracing. The attacks of coma are of so short duration that one will not remain for long undecided as to whether or not the condition is due to alcohol poisoning.

Sunstroke often simulates alcoholic coma and at times will cause confusion. The occupation, the time of year, the mode and suddenness of the onset of coma, the extremely high temperature together with the contracted pupils should be sufficient to prevent an undue number of mistakes.

The list of differential diagnoses might be indefinitely prolonged. General paresis, cerebral syphilis, meningitis and brain tumor should all be considered. So that while it must be admitted that it is quite possible to diagnose correctly many cases of alcoholic coma, yet one will agree that numerous surprises are in store for those who are too eager to accept things as they apparently are, and fail to realize the many possibilities that are presented by each case of alcoholic coma. Safety lies only in the process of exclusion, in the carrying out of which recourse must be had to the various diagnostic procedures which fortunately science has put at our command.

REPORT OF A CASE OF EXTIRPATION OF THE BLADDER FOR MALIGNANT DISEASE.*

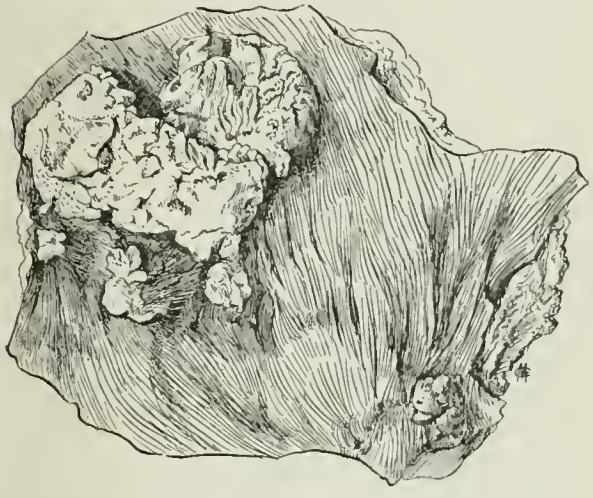
By FRANCIS R. HAGNER,

WASHINGTON, D. C.

PROFESSOR OF GENITOURINARY SURGERY, GEORGE WASHINGTON UNIVERSITY; ATTENDING GENITOURINARY SURGEON, GEORGE WASHINGTON UNIVERSITY HOSPITAL AND GARFIELD MEMORIAL HOSPITAL.

While there are a number of cases of total extirpation of the bladder that have been reported in literature, the procedure is so radical and the results following it are so interesting that I feel it might be of value to report the present case, although the end result was unsuccessful.

L. F., age 40, a Russian, was seen by me during the latter part of November, 1911. He presented the following history: He had hematuria of two years' duration, and painful and gradually increasing frequency of urination. His urine was very offensive and filled with blood and pus. At times the urination would be as often as every fifteen minutes, accompanied with great tenesmus. Again it would not be oftener than every one and a half hours. The more frequent the urination the greater the pain and tenesmus. Following the passage of the urine, which during the last six months was always blood-tinged, there would be the escape of almost pure blood. The patient was cystoscoped November 28. On rectal examination the prostate and seminal vesicles showed no evidence of malignant disease, being of normal size and shape. The bladder capacity was 125 c.c. After the instillation of adrenalin a satisfactory cystoscopic examination could be made, and a large irregularly shaped tumor with a broad base involving the entire base of the bladder was observed. The size of the base of the tumor was easily seen with a retrograde cystoscope. On December 5, a suprapubic cystotomy was performed under cocaine and adrenalin anesthesia. At the time of operation the cystoscopic findings were confirmed, and a suprapubic drain was inserted. The patient was much more comfortable after this operation and his general condition improved. As the patient was in fairly good condition, the gravity of the case was explained to him and he was advised to have the operation as advocated by Dr. Watson of Boston,



Sketch of extirpated bladder; one-quarter actual size.

namely, double nephrotomy with continuous drainage of the kidneys and subsequent removal of the bladder. The patient refused this operation as he said he did not wish his urine running out of his back. It was then explained that the ureters could be transplanted into his rectum. This he decided to have done. He was operated upon December 15, under nitrous oxide and oxygen anesthesia. The bladder was irrigated through the suprapubic wound and the opening packed with gauze to prevent any leakage into the peritoneal cavity. An incision was made from a point just above the suprapubic incision in the skin to just above the umbilicus. The intestines were pushed aside and packed off and the ureters were exposed; the left ureter was quite distended with urine on account of the involvement of the left ureteral orifice by the growth; the ureters were dissected down toward the bladder and clamped about 4 centimeters from their vesical orifices. The ureters were then incised, and the portion left attached to the bladder was well cauterized with carbolic acid and ligated. The operation chosen was Fowler's. The ureters were first sutured together in juxtaposition so that the lower ends ran parallel with each other. A longitudinal incision of 5 centimeters was made into the rectal wall down to the mucosa, and the muscularis and peritoneal coats were dissected and retracted. A U-shaped flap was then made through the submucosa into the gut; this flap was folded on itself and turned outwards, being held in place by two sutures so as to

*Read before the American Association of Genitourinary Surgeons, Philadelphia, June, 1912.

have a mucous surface for the ureters to lie upon, to thereby get the valve effect of the everted intestinal wall on the ureters. An attempt was made to clip the ureteral ends obliquely that they might lie flush on the intestinal flap; this was found to be more theoretical than practical, as the minute the ureter was obliquely cut the cut end became perfectly round. The ureters, stitched together as described, were placed on the folded piece of mucous membrane and held in place by four sutures into the submucosa. The muscularis and peritoneum were then brought over and the rectal wound was closed. The peritoneum of the abdominal incision was then closed, and the attention directed to the bladder. It was with comparatively little difficulty that the peritoneum was stripped and the bladder and the rectum separated from the base. At this time the patient's condition grew desperate and the operation had to be finished very rapidly. I had intended to remove the prostate with the bladder, as the growth, while not involving the prostate, was very near its posterior border. However, I did dissect the bladder down as near to the prostate as possible. After removal of the bladder the vessels were tied and the cavity was packed with sterile gauze, and the abdominal wound was closed, allowing vents for drainage. Before closure of the abdominal wound gauze was packed down to the point of anastomosis of the ureters and rectum for drainage. This, however, was unnecessary, as there was never any leakage, the anastomosis holding perfectly.

The patient was severely shocked from the operation, although the loss of blood was very small. Under stimulation and salt solution he rallied and did fairly well for one week; it appeared he was going to recover from the operation. However, he complained bitterly of stinging in the anal region and great tenesmus whenever urine passed; there appeared to be no pain while the urine was collecting in the bowel. Sometimes he would retain his urine one and a half hours. It was a continual fight to get this patient to take his nourishment. He seemed to give up after the operation, making no effort to help us in any way. There was no evidence of any abdominal infection and the one symptom he complained of was the pain and tenesmus during the passage of urine out of the rectum. The patient had very little fever, but a rapid pulse and a leucocytosis of 26,000. Unquestionably there was infection of both kidneys. He gradually grew weaker and died two weeks after the operation. I endeavored without success to secure an autopsy.

I feel that if I had insisted on the two-stage operation, double nephrotomy and removal of the bladder at a subsequent operation, the result might have been different. The valve-like operation for anastomosis is very satisfactory and beautiful to perform, but I question if these valve-like operations for ureterointestinal anastomosis would be permanent on account of the resulting scar tissue obliterating the valves.

The Farragut.

The Extent of Leucocytic Proteolysis.—J. W. Jobling and S. Strouse state that the proteolytic action of leucocytes is not a simple cleavage by one ferment. There are present two proteases, one acting in an alkaline medium and the other in an acid medium. This confirms Opie's work. In the leucocytes there was found in addition an ereptic ferment which is capable of acting in an acid or alkaline medium. This action probably represents a ferment which acts on the digestion products of the two proteases.—*Journal of Experimental Medicine.*

CELIAC PAROTITIS IN THE COURSE OF MALIGNANT DISEASE OF THE LIVER.

By DAVID I. MACHT, M.D.,

BALTIMORE, MD.

Secondary parotitis in various abdominal conditions, or as Dyball calls it "celiac" parotitis, is an extremely interesting condition, as pointed out by Osler[1] and first described by Stephen Paget,[2] whose reports appearing in 1886 and 1887 are still the most important contribution on the subject. Sporadic cases have been more lately reported by a number of observers[3] but altogether the condition is barely touched upon in most textbooks. Thus Kraus in Nothnagel's "Handbuch" hardly mentions it. Paget describes the disease as an inflammation of one or both parotid glands, leading to suppuration or not, and occurring after injury or disease of the abdomen or pelvis. He analyzed in all 101 cases. Of these 10 followed injuries of the urinary tract; 18 followed injury or disease of the alimentary canal; 23 followed injury or disease of the abdominal walls, peritoneum, or pelvic cellular tissue, and 50 followed lesions of the generative organs. Of the 101 cases 37 died, 3 of the patients being over 80 years old.

The injuries after which this secondary affection of the parotid glands may occur range from the slightest, such as the introduction of a catheter or a pessary, to those following very severe abdominal operations. The diseases of abdominal viscera associated with the secondary parotitis are also very different: perforation of the bowels, hernia, syphilis, pelvic inflammatory disease, typhoid fever, gastric ulcer, cholecystitis, appendicitis, etc. In this paper I wish to report a rare case of parotitis occurring in the course of malignant disease of the gall-bladder and liver. On looking over the literature on the subject, I find internal cancer or other malignant growths to be very rarely associated with the affection. Paget's series, which is the longest, includes only three such cases (cases No. 18, 26, and 39), which were malignant growths of the spine, the sigmoid flexure, and the ovary, respectively. I could not, however, find any reference to a case of parotitis associated with hepatic disease, either in his papers or in Rolleston's comprehensive treatise on diseases of the liver and bile-ducts, or in any other publications. For this reason I think the following history to be of interest.

Mrs. H. F., widow, 72 years old, was first seen by me June 3, 1912. She complained of jaundice. The family history was negative; there was no tuberculosis or cancer in the family.

Personal history: Patient was remarkably free from disease in her past life. She remembered not having had any children's diseases. There was no history of typhoid fever, pneumonia, rheumatism, or lues. She had five children and no miscarriages. She had been a vegetarian for many years. Present illness: About two months ago patient noticed that she was jaundiced. She never had pain of any kind in abdomen or elsewhere, but came complaining of a failing appetite and loss of strength. She had lost about twenty pounds in two months. Her bowels were regular or slightly loose and the stools were white or clay-colored. She passed very dark-colored urine. She complained of a bitter taste in the mouth, but outside of the loss of appetite and failing weight and strength, there were no other symptoms. Physical examination: The patient walked with difficulty, as if she had no strength.

The entire body was pigmented a deep yellow, her face having a bronze-yellow tint. The skin was dry and wrinkled from the extreme and rapid loss of subcutaneous fat. The tongue was dry and heavily coated. The pupils reacted to light and accommodation. The chest was symmetrical but thin and its movements were equal on both sides. Lungs clear throughout on percussion and auscultation. Heart: The apex beat was in the fifth interspace in the mammary line. The cardiac dullness was not increased to right or left. On auscultation a very soft systolic bruit was heard at the apex. A systolic bruit was also heard in the aortic region (probably due to atheroma). Pulse: 68 to the minute; moderate volume; good tension; vessel-walls distinctly sclerosed. Abdomen: Flabby and soft. On the right side under the costal margin a mass was *visible* and palpable, extending about a hand-breadth below the costal margin; it was confined entirely to the right side of the abdomen. It felt slightly irregular and was not tender on pressure. Spleen was not enlarged. There were no prominent veins on the abdominal wall and there were no ascites. The lower extremities did not show any edema. Temperature 99° F. Stools clay-colored. Urine contained bile (usual tests). From the history of the case and the physical findings, a diagnosis of a malignant growth, probably carcinoma, of the gall-bladder and liver was made. The subsequent history confirmed the diagnosis.

Subsequent history: The patient's condition continued to decline very rapidly. One week after the examination she had to go to bed and stay there. She loathed the sight of all food and drink, and was lying drowsy and apathetic, and had a slight remittent fever. She developed the symptoms and signs of an extreme cholemia. There was a gradual wasting away, and in spite of all that could be done (which was indeed very little) she went into coma and expired on June 21, three weeks after I had first seen her. About five days before death the patient developed a marked swelling of her left parotid gland, which caused her a good deal of pain and interfered with deglutition. Two days later a similar though somewhat smaller swelling appeared on the other side. The double parotitis caused the patient more suffering than the whole previous condition. It gave her pain and interfered with deglutition and respiration. Dr. O. Pancoast, a surgeon, who saw the case with me, did not find any abscess formation and did not advise surgical interference. The treatment remained entirely symptomatic. Unfortunately I was unable to get permission to perform an autopsy on the patient, but the post-mortem findings described by Paget in one of his cases would seem to fit very well with our clinical picture. In Paget's case a woman developed a parotitis after she was operated on for a sarcoma of the mesentery. The parotid gland was enlarged, but had no pus or abscess. It was found to be evenly distended with a reddish substance somewhat like spleen.

What the connection may be between the abdominal conditions and parotitides mentioned above is largely a matter of conjecture. Dyball,[4] who discusses the various theories advanced in explanation of it, sums up his views as follows: "It appears most probable that celiac parotitis is due to the action on the parotid glands of toxic substances absorbed into the blood and derived from (a) the secretions of certain organs modified by injury or disease; (b) toxins of microbic origin (*e.g. Bacillus coli*), absorbed either from the alimentary canal, peritoneal cavity, or bladder, and (c) products of deranged digestion." Which of these factors played the important rôle in my case I will not venture to say.

1511 Madison Avenue.

Chronic Jaundice and Splenomegaly.—L. Guthrie reports the case of a girl, aged 6 years, who eighteen months ago became jaundiced. Icterus has varied in intensity from time to time, but has never disappeared entirely. The urine is sometimes dark in color but usually pale, and the stools are said to be always dark brown. She often complains of feeling sick, but seems well on the whole. Past illnesses: Varicella and pertussis at 3 years, "rheumatic fever" at 5 years, and morbilli at 5½ years, followed by chorea. Has always been troubled with thread-worms. Family history: Parents, and brother and sister, aged 10 and 13 years, are in good health. No miscarriages. No children have died. Present condition: Fairly well nourished blonde. On admission to hospital, December 11, 1911, the skin, mucous membranes, and conjunctivæ were of bright canary-yellow color. Bowels constipated, motions dark, containing much mucus, but no oxyurides. Urine pale, no bile pigment, acid, 1015, no albumin. Heart and lungs normal. Liver not felt, area of dullness normal. Spleen easily palpable, extending 2 inches below costal margin. Notch not felt. Blood examination: Serum is colored deep yellow. Reds, 4,190,000; whites, 10,200; hemoglobin, 80 per cent. Differential count: Polymorphonuclears, 76 per cent.; large lymphocytes, 4.5 per cent.; small lymphocytes, 17 per cent.; eosinophiles, 2.5 per cent. During three months' observation, the icterus has varied greatly in intensity but has never quite disappeared. The stools are always dark, and the urine has never contained bile pigment. The spleen is still enlarged. The area of hepatic dullness is normal. The probable diagnosis is: Toxic hepatic cirrhosis with splenomegaly.—*Proceedings of the Royal Society of Medicine.*

Papilloma of the Trachea in a Woman, aged 24.—W. H. Kelson reports the case of a married woman who gave no history of tuberculosis or syphilis. She stated that difficulty in breathing commenced a year ago, and that it became noisy three months ago, getting gradually worse. On examination it was found that the larynx was normal. At about 1 inch below the level of the cricoid cartilage and taking origin posteriorly from the tracheal wall a growth was seen. There was marked stridor, but no expectoration. No enlarged glands. Many rhonchi and other abnormal sounds were heard in the upper part of the chest, so that tuberculosis was suspected. The growth was removed by the direct method without tracheotomy under a general anaesthetic, with immediate relief to the breathing and the disappearance of the chest sounds. It appeared to be a papilloma.—*Proceedings of the Royal Society of Medicine.*

Aortic Regurgitation with Extreme Pulsation of the Aortic Arch; Diastolic Shock and Diastolic Thrill Over the Heart.—F. Parkes Weber, M.D., reports the case of a woman, aged 28, who during the last month has suffered from severe pain in front of the chest. When aged 15 she had rheumatic fever, and her heart has been said to be "weak." Above the level of the heart to the right of the sternum there is a loud systolic murmur to be heard, and pulsation can be felt, accompanied by a marked systolic thrill. There is much pulsation in the episternal notch. The cardiac apex-beat is displaced to the left axillary region. Over the aortic base there are both loud systolic and loud diastolic murmurs. Over the mid-cardiac region there is a loud diastolic murmur, accompanied by a diastolic thrill. With the flat of the hand placed over the heart the diastolic thrill can be felt as if travelling from the aortic base towards the cardiac apex. About the nipple line, in the fifth left intercostal space, a diastolic shock can be felt, which might possibly at first be mistaken for the apex-beat. The Wassermann reaction is positive.—*Proceedings of the Royal Society of Medicine.*

FEEBLEMINDEDNESS IN NEW YORK.

IT is a most difficult problem to obtain reliable and complete data on the prevalence and actual importance of feeblemindedness in a community. Particularly is this true of New York City, in which the diverse elements of race, language, and religion make the exact determination of this factor almost impossible. The most thorough study so far made of this subject in New York is summarized in a report rendered to the Public Education Association of New York by Dr. Anne Moore.

The case histories on which this report is based illustrate very clearly the difficulty of proper segregation of defectives under the present laws and state provision. They further make very plain the demand on the resources of the city's public schools, and the serious results which follow the free presence of feebleminded persons in the community, such as the production of defective offspring, the indulgence of criminal and immoral tendencies, and the drain on the resources of the family and of charity. In the face of this evidently serious situation, it is a strange fact that there is no legal provision for mental defectives in the public schools. The Compulsory Education Law exempts from school attendance children who are "physically or mentally unfit," the ones who of all others most need it. Recognizing that the presence of backward children is undesirable in the same classes with normal children, the Board of Education has established certain ungraded classes for them, in which they can receive special training suited to their needs. Defective children are reported to the inspector of ungraded classes and after examination by a physician are assigned to a class if their condition justifies it. About 2,000 defective children are cared for in the 125 ungraded classes of Greater New York. Unfortunately the training most of these children receive ceases when they leave the class. Were it continued, many of them could be made useful, happy, and at least partially self-supporting. The classes are seriously handicapped at present by the lack of a proper segregation law providing for the enforced attendance of defective children and for the continuance of their training after they reach the legal age limit of sixteen years. Such a law would also remove the effects of ignorant opposition, and should provide for the transfer of cases more properly belonging in custodial institutions, thus relieving the overcrowding of the ungraded classes, to the advantage of the less deficient children who would profit most by the training.

Five institutions have been established in New York State for the care of the feebleminded. The capacity of these institutions is so lamentably inadequate that large numbers of mental defectives are at large. Moreover, they provide only for indigent defectives; the large middle class which can afford a moderate expense for institutional care usually will not accept charity, and cannot afford the expensive private institutions. At present there is no law requiring the commitment of the feebleminded to custodial institutions. Consequently it usually rests with parents or guardians to decide the question, and they are too often incapable of knowing or doing the best thing for the child or for the community. It costs the State an average of $161.20 annually to care for a feebleminded person in an institution. It is impossible to estimate the cost of such a person at large. His tendency to produce defective offspring, his inability to become self-supporting, when subjected to present day competition, and his large share in the criminal class all combine to increase his actual expense to, and drain on, the community. Dr. Moore very correctly points out that the segregation of defectives costs money, but saves much more than it costs. The best interests of the community demand segregation in proper institutions, and in addition no marriage license should be issued without a clean bill of health and evidence of a normal mind.

TESTING INDOOR AIR.

FOR many years sanitarians and hygienists have desired earnestly some ready test for the purity of room air without reference to CO_2 comparable, say, to the permanganate test for pure water. This necessity is even greater for schools, hospitals, barracks, etc., than for private houses. Tests of this sort have long been employed, but the results have been susceptible of different interpretations. In recent years attempts have been made to determine not only the kind, but the quantity of organic impurities. Naturally such tests demand such extreme delicacy that only the method of catalysis could be expected to give results of any sort. If this principle is found to be trustworthy for the estimation of expired substances it would naturally be available for impurities generated in manufactures of various kinds, in which artificial substances are added to the product of human lungs. In the case of workingmen who exert much muscular activity it should also be possible to recognize the added production of waste substance. The new avenues thus opened to study, if we suppose that delicate catalytic tests become practicable, are not a few; and it must be borne in mind that the very delicacy of the tests, as happens so frequently elsewhere, may be a bar to their utilization.

In the *Münchener medizinische Wochenschrift* for August 27 Weichardt and Kelber discuss this subject in a brief but highly suggestive fashion. An apparatus is required for obtaining specimens of

air for analysis which combines all the most recent utilizable principles. There is an air pump worked by a motor, a gas meter, wash bottles, etc. The air is forced through glass pearls which contain glycerine solutions of various catalysts.

Colloidal osmium is used as an indicator for the presence of extraneous matter, but it is necessary further to use a color test to make the catalytic action visible. This is effected by the presence of a solution of starch in a solution of potassium iodide with the addition of oil of turpentine. The normal appearance of the blue color indicates that the air is sufficiently pure. If the color reaction is absent or imperfect deleterious substances are present in the expired air. The presence of carbon dioxide alone exerts hardly any influence on the catalysis. The test for purity of air, as already suggested, corresponds roughly in its general outcome with the test for organic matter in water with potassium permanganate.

THE ASSAULT ON MR. ROOSEVELT.

The attempted assassination of Mr. Roosevelt last Monday evening was fortunately frustrated by the spending of the force of the bullet in passing through a thick overcoat and coat and a package of manuscript and by its deflection by a spectacle case. The bullet was on its way to pierce the lungs and possibly one of the large vessels or some other vital part when it met these obstacles and was turned upward, lodging in the tissues of the chest wall. If the newspaper accounts are correct the intended victim is suffering from a wound of slight moment, despite a broken rib, and had he been an ordinary citizen his case would have given the surgeons but little concern. Of course there was a minute chance of tetanus and a somewhat greater one of suppuration in the wound and possibly of pyemia, but these chances were so small that, the proper precautions being taken, they would have caused little apprehension ordinarily. It was characteristic of the man that he disregarded the injury to his chest and delivered a long political speech before receiving medical attention. In the case of the ordinary citizen again, this would have been called foolhardy and might have had most serious consequences; doubtless it was done in face of the protest of his medical advisers, but it apparently did him no harm.

With fear for the life of the patient allayed, one's thoughts naturally turn to the fact of the attempted assassination, associating it with the murders of Garfield and McKinley. There seems to be no possible way of shielding a public man from the murderous attack of a paranoiac. This is one of the dangers to which he is exposed by virtue of his calling, and is no more to be guarded against than is any other accident. It is obviously impossible to shut up all "cranks," even were it possible to pick them out and to draw the line between the simple fool and the dangerous paranoiac. No form of punishment would deter certain of these degenerates from their criminal attempts. Solitary confinement, the most fiendish and horrible of all punishments, which is meted out to the assassins of the Italian kings, does not stay the hands of others. We can, therefore, only guard our public men the best we can, and hope that, if they are attacked, they will have the good luck which has been Mr. Roosevelt's, and over which everyone, politically friend or foe, can but rejoice with all his heart.

Puerperal Tetanus.

Tetanus in the puerpera furnishes a special opportunity for the study of this still mysterious disease. The difficulties attendant upon infection in many puerperal cases, the differences in findings, the extreme mortality of the type, all demand special consideration. In a paper read recently before a Strassburg medical society (*Deutsche medizinische Wochenschrift,* September 19) Freund reported three fatal cases of puerperal tetanus. One followed manual delivery, the others were abortions induced by introducing familiar objects, one wooden, into the uterine cavity. In none of these cases was there found any trace of a bacillus, either in the uterine secretions, the dust, or garden soil. Animal inoculations were also negative throughout. Tetanus antitoxin had absolutely no favorable influence, while opiates gave temporary relief. In this connection Freund cited a case of tetanus neonatorum due apparently to the application of wood dust in the umbilical stump. In this case, in contrast to the preceding, the tetanus germ was found in both the secretion of the navel and in the wood dust. The paper gave occasion for considerable comment. One member of the society cited a case of inversion of the rule that prolonged incubation means a more favorable prognosis. In a case of only two days' incubation period, recovery promptly followed antitoxin exhibition. Unusual was the fact that in this case injury of the knee was first succeeded by stiffness of the corresponding leg. Only later did tetanus proper follow. Ledderhose is so impressed with the frequency of splinters and other wooden articles in causing lockjaw that he always insists on a prophylactic injection of antitoxin in wounds of this type.

An "Anatomical Demonstrator."

The list of freaks who go from clinic to office and who often derive their subsistence from demonstrating their peculiarities to physicians and students appears to be constantly increasing. There is the subject with the absence of pharyngeal reflex, perhaps a stigma of hysteria, who allows her larynx to be studied; the man with the musical heart murmurs, who is ornamental rather than useful, and the man with the double singing voice who is a vaudeville headliner and does not have to eke out a livelihood from the doctors. This list might be extended almost indefinitely if we include the museum freaks and those who in general appeal chiefly to the public curiosity: but even those who interest the profession only are sufficiently numerous. According to German exchanges one Franz Boehner has appeared before nearly all the clinics and medical societies in Germany. He styles himself an "anatomical demonstrator," but is not a contortionist or an artist's model. His remarkable control of groups of muscles enables him to simulate at will various spastic and paretic conditions. He reproduces ptosis, various forms of strabismus, mydriasis and myosis, nystagmus, cutis anserina, etc. He is able to change the position of the heart and other viscera, can slow his pulse, and force a bolus of food from mouth to anus in 45 minutes. His ability is due to voluntary control of muscular fiber commonly classed as involuntary.

News of the Week.

Excess of Males.—The population of the United States comprised in 1910, according to the Federal census, 47,332,277 males and 44,639,989 females, or 106 males to every 100 females. In 1900 there were 104.4 males to every 100 females. This excess of males is due mainly to the extensive immigration, the foregn-born white population numbering 129.2 males to 100 females. In the native-born white populaton the ratio is 102.7 to 100. In the negro populaton, however, the females outnumber the males, the ratio being 98.9 to 100. The preponderance of males is most marked in the Pacific and Western States, while in the New England States the females are slightly in excess. In New York City the population is about evenly divided as regards sex, while in Philadelphia there is a preponderance of females, and in Chicago there are 106.3 males to 100 females.

Vital Statistics of Texas.—During the month of August there were reported to the State Registrar 4,844 births and 2,032 deaths. As compared to the previous month this shows an increase of 480 births and a decrease of 311 deaths. There were 412 deaths of infants under one year of age and 184 from tuberculosis, which was the leading cause of death during the month.

Births in Chicago.—During the first nine months of this year 31,346 births were reported to the Health Department of Chicago, an increase of 9,878, or about 46 per cent. over the number reported during the same period of 1911.

Doctors Pledge Autopsies.—The members of the Associated Physicians of Long Island at a recent meeting adopted a resolution prepared by a special committee, setting forth the need of educating the public to a better understanding of the value of autopsies in the advancement of medical science. In the adoption of the report many of the physicians present agreed to sign a form containing a request that in the event of death their heirs consent to the performance of an autopsy, since it was their opinion that in beginning a campaign of education to overcome the popular dislike of a post-mortem examination it was the duty of the physicians themselves to set an example.

Gifts to Columbia.—The Trustees of Columbia University at a recent meeting announced that by the will of the late Mr. Augustus W. Openhym, the university will eventually come into the possession of a fund, to be known as the Openhym Research Fund, and to be used for research into the cause, prevention, and cure of cancer. If at any time further research into cancer becomes unnecessary the income of the fund may be used for other researches in the field of medicine and surgery.

A gift of $2,500 from Mr. Clarence H. Mackay for surgical research was also announced, as well as anonymous gifts of $1,800 for the department of materia medica, and of $1,000 for the department of physiology.

Pure Water Oysters Only.—Health Commissioner Lederle of New York City has notified dealers and shippers of oysters in New York that before their permits will be renewed they must file with the Health Department exact information as to the name of the grower of the oysters handled, the location from which the oysters are obtained, and the definite location of "drinks," if any, and, most important, absolute proof of the purity of the waters in which the oysters "drink" or are freshened up for market. The Commissioner believes that the greatest danger of contamination occurs in the freshening beds or "drinks." These new rules will cover not only the oysters grown here, but also those shipped in from outside. Dr. Lederle has again declared that in spite of the Government's finding that the waters of Jamaica Bay were not all that they should be, the Health Department had not been able to discover anything wrong there—a declaration which is not altogether reassuring to oyster eaters.

Concession to English Physicians.—It is reported that the physicians in England have been offered a substantial increase in the sum allotted to them under the Insurance Act. The Government, which at first offered 1.08 per insured person a year, and later offered 1.44, has now by increasing the appropriation made possible the payment of 1.80. The doctors had declared that 2.04 was the least they would accept.

University Hospital.—Columbia University, New York, has undertaken to oversee the health of its students, and has opened a miniature hospital on the university grounds under the direction of Dr. W. H. McCastline, who is connected with the department of physical education of Teachers' College. An office has been opened in Earl Hall, which is equipped with the simpler devices of the operating-room, and in addition includes a laboratory for the examination of the eye, ear, nose, and throat, and apparatus for dental work. The University requires that all cases of illness be reported to Dr. McCastline, whether in the student's home or in the dormitory.

198th Aviation Victim.—With the death of Joseph Stevenson, who fell from his biplane during an exhibition flight at the Alabama State Fair Grounds in Birmingham on October 7, the total number of aviation victims since 1908 is increased to 198, of whom 87 have been killed during the current year.

City Vital Statistics.—During the month of September the death rate in New York City was 12.11 per thousand, the lowest on record for that month. The total number of deaths was 5,149, as compared to 5,331 in September, 1911, when the rate was 13.1 per thousand. For the month of September the average for the preceding fourteen years was 15.53. All of the age groups show a decreased mortality except that from 45 to 65 years, in which there is a slight increase. During the same month 10,951 births were reported, an increase of 142 over that period last year, while the number of marriages reported was 4,089, a decrease of 13.

During the week ending October 5 there were 1,274 deaths in the city, of which 271 were of children under one year of age, as against 1,204 in the corresponding week of last year, of which 301 were of children under one year. For the first forty weeks of 1912 the death rate was 14.30 in the city, while for the same period of 1911 it was 15.56.

Diphtheria Epidemic.—Forty cases of diphtheria have developed in the mill towns of Webster and Dudley, Mass., within the last few days and strenuous efforts are being made to check the spread of the disease.

Restrictions on Sale of Milk.—The New York City Board of Health has recently passed resolutions strengthening the safeguards which surround the sale of milk in the city. After June 1, 1913, it will be illegal to sell milk dipped from cans except in approved milk stores under permits from the

Board of Health, and in stores in which foodstuffs other than milk are sold in the original packages only. It is estimated that 800,000 quarts of loose or dipped milk are sold each day in the city, and the problem of guarding this supply has been one of the chief objects of the department.

Lectures on Hydrotherapy.—Dr. L. Brieger, professor of therapeutics and special pathology in the University of Berlin, Germany, lectured by invitation of Dr. Baruch to the students in the Hydrotherapeutic Department of the Vanderbilt Clinic, College of Physicians and Surgeons, on October 9. Dr. Brieger demonstrated a hydriatic method of treating sciatica, devised by himself, consisting of active and passive movements designed to put the nerve on the stretch, together with firm trembling pressure upon the painful spot, first gentle, then increased, until no pain is produced. After the painful parts have been subjected to steam douches of ten minutes' duration, these movements are made while the patient is submerged in water at 95°, reduced at each treatment. The demonstration was successful, the patient expressing himself as greatly relieved and able to walk with ease.

New Tuberculosis Hospital.—The Municipal Tuberculosis Hospital in Yonkers, N. Y., was formally opened on October 12 and was ready on the 14th for the reception of patients, of whom forty had made application before the opening. The building, which cost about $1,500,000, has been erected on a five-acre plot given to the city by Mr. A. S. Cochran.

Yellow Fever from Brazil.—A well-developed case of yellow fever was discovered among the crew of the British steamer *Chaucer,* which arrived at the New Orleans Quarantine Station on October 8, from Brazilian ports. The patient was sent to the detention ward of the Marine Hospital and the vessel was held in quarantine for six days. No apprehension is felt as to the danger of spread of the disease.

Cases of Hookworm.—The Rockefeller Commission for the study of hookworm disease in Alabama reports that from January 1 to September 30 of this year 8,685 cases of the disease were observed in twenty-two counties of the State. That the work of the commission is increasing is shown by the fact that during the first six months of this period 5,334 cases were observed, while during the last three the number reached 3,351. Most of the patients were treated in the dispensaries established by the Commission.

To Study Malaria.—Dr. J. M. Jackson, president of the Southern Medical Association, has appointed a commission to take up the study of means for the prevention of malarial fever, consisting of Dr. Charles F. Craig, U. S. A., Washington, chairman; Dr. Graham E. Hanson, Crescent City, Fla., secretary; Dr. R. H. Von Erzdorf, U. S. Public Health and Marine-Hospital Service; Dr. Seale Harris, Mobile, Ala., Dr. William Krause, Memphis, Tenn., Dr. Creighton Wellman, and Dr. C. C. Bass, New Orleans, La., Dr. William H. Deadrick, Marianna, Ark., and Dr. W. S. Thayer, Baltimore, Md.

Poliomyelitis in Los Angeles.—A correspondent writes that the report of an epidemic of infantile paralysis in Los Angeles during the past summer was greatly exaggerated. Instead of a total of 226 cases with 43 deaths, a committee of physicians found that there had been only 23 authenticated cases with 3 deaths.

German Physicians Sail.—The delegation of German physicians, 225 in number, who came to this country to attend the sessions of the International Congress of Hygiene at Washington last month, sailed for home on the *Victoria Luise* from New York on October 10.

Radium in Springs.—Analysis of the waters of the lava hot springs at Dempsey, Idaho, has shown, it is said, the presence of radium, and further investigations are to be made to determine the existence of deposits in the vicinity. The springs belong to the State, having been taken over several years ago, and have long been noted for their healing power.

Beriberi on Shipboard.—With three of her crew dead and six others ill with beriberi, the bark *Daylight* reached Philadelphia on October 6 after a 125-day voyage from Bombay, India. The ship was held at Quarantine for several days.

Inspection of Railroad Trains.—The Surgeon-General of the Public Health and Marine-Hospital Service has been instructed to inspect the features of railroad trains and vessels engaged in interstate commerce. As a result it is expected that the railroad trains and passenger carrying vessels will be cleaned up a bit and made more sanitary, and that the Government's interest in the matter will prompt the managers of such lines to have fumigation carried on at certain intervals, especially in parts of the country where there is a constant movement of persons afflicted with tuberculosis. As there is at present no appropriation available for defraying the cost of the inquiry the members of the service will be obliged to conduct it at times when orders for travel are issued for other duties.

Civil Service Examinations.—The New York State Civil Service Commission announces that examinations will be held on November 2, 1912, for the purpose of filling the following positions: Medical librarian, State Library, at a salary of $1,200 to $1,500. Physical instructor, women only, at a salary of $540 and maintenance. Sanitary inspector, Ossining, at a salary of $720. In the last case, residence for three months in the town is required. Application blanks must be filed on or before October 25, 1912. Full particulars may be obtained from the State Civil Service Commission, Albany, N. Y.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $180, will be made on July 14, 1913, provided that an essay deemed by the Committee of Award worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine and must be unpublished. They must be typewritten in English or accompanied by an English translation, and received by the secretary of the college on or before May 1, 1913. Each essay must be sent without signature, but must be marked and accompanied by an envelope bearing the same mark and containing the name and address of the author. The successful essay or a copy of it remains in the possession of the college.

Weir Mitchell Lectures.—The sixth of the Weir Mitchell Lectures of the College of Physicians of Philadelphia will be delivered on Monday evening, October 21, 1912, at 8.15 o'clock, in Mitchell Hall, by Prof. G. H. F. Nuttall, M.D., F.R.S., of Cambridge, England. The subject of the lecture will be: "Some Recent Advances in Our Knowledge of the Mode of the Spread of Protozoal Diseases."

Lectures on Skin Diseases.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley will give a fourteenth series of clinical lectures on diseases of the skin in the Out-Patient Hall of the Hospital, Second avenue and Nineteenth street, on Wednesday afternoons, from October 30 to December 18, 1912, at 4.15 o'clock. The course will be open to physicians on the presentation of their professional cards.

Nobel Prize Award.—The Nobel Prize in Medicine for 1912 has been awarded to Dr. Alexis Carrel of the Rockefeller Institute for Medical Research, New York, for his work in the suturing of blood vessels and the transplantation of organs. The prize amounts to $39,000. Dr. Carrel, who was born in France thirty-nine years ago, has been connected with the Rockefeller Institute since 1906, and is now an associate of the Institute. He is a Fellow of the American Surgical Association, and a member of the American Philosophical Society.

Medico-Chirurgical College of Philadelphia.—The following elections have been announced: Dr. Stillwell C. Burns, to be professor of operative surgery, in succession to Dr. Mitchell F. Warmuth, resigned; Dr. Robert Boyer, to be demonstrator of anatomy, in succession to Dr. Van Duyne A. Sutliffe, resigned; and Dr. L. Napoleon Boston, to be professor of physical diagnosis, in succession to Dr. Howard S. Anders, resigned. In addition, Dr. Herbert M. Boyer has been appointed demonstrator of histology and embryology, Dr. John J. Gilbride, demonstrator of surgery, and Dr. Philip Fichelis, secretary and librarian, in succession to Dr. A. C. Morgan.

Personals.—Dr. B. Sachs of New York announces his removal to 116 West 50th street.

Dr. Walter S. Reynolds of this city has removed to 132 West 73d street.

Dr. Hobart A. Hare of Philadelphia has been appointed a member of the Board of City Trustees of that city.

Dr. Mary Almira Smith of Boston received the honorary degree of Doctor of Letters from Mt. Holyoke College at the celebration of its seventy-fifth anniversary on October 9.

Dr. Benjamin P. Watson of Edinburgh, Scotland, has accepted the appointment as professor of gynecology and obstetrics in the University of Toronto, Faculty of Medicine, and will assume his new duties on November 1.

Gifts to Charities.—By the will of the late Mrs. Marion de Forest Clark of New York, the New York Society for the Ruptured and Crippled and the New York Orthopedic Dispensary and Hospital receive bequests of $7,500 each.

By the will of the late Sarah I. Wohlgemuth of Philadelphia, a residuary bequest of $5,000 is made to the Presbyterian Hospital of that city to endow a free bed in the men's ward in memory of her father, and in addition the sum of $5,000 to endow a free bed in the women's ward of the same hospital in memory of her mother.

The Medico-Chirurgical Hospital of Philadelphia receives a bequest of $500 by the will of the late Katherine Shoemaker of that city.

The Society of Sanitary and Moral Prophylaxis.—A meeting of this society will be held in connection with the New York Association of Biology Teachers at the Academy of Medicine on Thursday evening, October 24, at 8.30 P. M. The subject for discussion will be the report of the special committee of the American Federation for Sex Hygiene (Dr. Prince A. Morrow, Prof. Maurice A. Bigelow, and Prof. Thomas M. Balliet) on the Teaching of Sex in Schools and Colleges.

Colorado State Medical Society.—At the annual convention of this society held in Pueblo the following officers were elected on September 26: *President,* Dr. John A. Black, Pueblo; *Vice-Presidents,* Dr. Carroll E. Edson, Denver; Dr. William Henry Hally, Rouse; Dr. Henry A. Calkins, Leadville, and Dr. Charles A. Ringle, Greeley. The next annual meeting will be held in Glenwood Springs on October 7, 8, and 9, 1913.

Association of Military Surgeons of the United States.—The following officers were elected at the twenty-first annual meeting in Baltimore recently: *President,* Surgeon William C. Braisted, U. S. N.; *Vice-Presidents,* Brig.-Gen. Charles Adams, Illinois National Guard; Lieut.-Col. J. R. Kean, U. S. A., and Surgeon-General Rupert Blue, U. S. P. H. and M.-H. S.; *Secretary and Editor,* Major Samuel C. Stanton, Illinois National Guard; *Treasurer,* Major Herbert A. Arnold, Pennsylvania National Guard. Denver was chosen as the meeting place for next year.

Cape Breton (N. S.) Medical Society.—At the annual meeting on September 24, in Sydney, the following officers were elected: *President,* Dr. Andrew Love, Sydney Mines; *Vice-President,* Dr. John Knox McLeod, Sydney; *Secretary-Treasurer,* Dr. John G. B. Lynch, Sydney.

Obituary Notes.—Dr. William Brewster Clark of New York, a graduate of Amherst College in 1876 and of the College of Physicians and Surgeons in 1879, a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the Greater New York Medical Association, and the Society of Sanitary and Moral Prophylaxis, died at his home on October 11 after several months' illness, aged 62 years.

Dr. Arthur Hugo Friedeberg of St. Louis, Mo., a graduate of Washington University, Medical Department, St. Louis, in 1904, died suddenly on September 28 from strangulation following the lodgement of a fishbone in his throat.

Dr. John Jay Colton of Lowell, Mass., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1869, a member of the Massachusetts State and Middlesex County Medical Societies, and formerly city physician of Lowell, died at his home on September 23, aged 82 years.

Dr. R. J. Grimes of Bethel, N. C., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1876, and a member of the North Carolina State and Pitt County Medical Societies, died at his home of appendicitis on September 28, aged 62 years.

Dr. Charles Nelson Ballard of Oklahoma City, Okla., a graduate of Rush Medical College, Chicago, in 1890, a member of the American Medical Association, the Oklahoma State and County Medical Societies, and the Illinois State Medical Society, died at his former home in Logansport, Ind., on September 21, after a long illness, aged 53 years.

Dr. Henry Johns Rhett of Washington, D. C., a graduate of Brown University in 1885 and of the University of Pennsylvania Department of Medicine in 1890, and a member of the Medical Society of the District of Columbia, died in the Newport Hospital, Newport, R. I., on October 7, aged 50 years.

Correspondence.

LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE: DANGER TO LIBERTY; LEGAL VIEWS OF THE REGULATIONS EXTENDING; STEPS TO ADMINISTER ACT TAKEN; RESOLUTIONS OF PRACTITIONERS AGAINST—EFFECT OF TUBERCLE ON RACE—EXHIBITION—HOSPITAL RESPONSIBILITIES—ITEMS.

London, September 27, 1912.

The manner in which the Insurance Act was rushed through Parliament has resulted in a striking illustration of a danger to liberty which has been gradually extended of late. The Cabinet has been indirectly aiming at the power of forcing its will by mere decrees, such as when directly issued have brought monarchs to ruin. The act set up an executive body—the Insurance Commissioners—and that body was authorized to issue rules and regulations which should become law as binding as the clauses of the act itself. Since the passage of the act the commissioners have been issuing regulations on numerous points, not a few of which could not have been anticipated, and are causing great discontent, but nothing can stay their hand except an address to the Crown by one of the Houses of Parliament. Such legislation is an abuse which has grown up to the peril of the liberty of the subject. The lawyers even are condemning it as a breach of the constitution.

At the annual meeting of the Law Society it was forcibly urged that from a national point of view the act would prove a crippled scheme with a hostile medical profession. The doctors were, it was said, the first line of defense against malingering and without their co-operation approved societies would undoubtedly, many of them, become bankrupt. The casual laborer had suffered much wrong, had often had to pay a double contribution—an employer's and his own—before he could get employment. The appointment of outside authorities under the act was only one instance of the evil extension of officialism. Actually, in connection with sanatorium benefit, six sets of authorities had to be consulted and satisfied in some cases. An amending act was necessary, agreed several speakers, as it was now recognized in all directions that without legislation it would be impossible to give satisfactory terms to the medical profession.

Rumors as to the scope of the regulations had for some time been plentiful and contradictory, but on Monday some of the papers issued a statement to the effect that a draft had been prepared which afforded hope for settlement and had been submitted to the sickness committee of the British Medical Association. In this it was said medical remuneration was left to the local health committees to arrange as to the capitation, or attendance, or special service system. It was added that Mr. Lloyd-George would probably submit to the Cabinet a proposal for a parliamentary vote of a percentage of the State Insurance Fund for payment of medical men—not a flat rate, but differing according to the circumstances of different districts. The next day the secretary of the British Medical Association informed the press that no draft of proposed regulations had been received—nor probably would be until made public generally. To this denial one of those who supplied the statement replied that the committee's information was only "unofficial," the advantage of that distinction being that similarly unofficial suggestions may be received by the commissioners and considered before finally adopting the draft "officially."

He further declared that the facts he had communicated as to these regulations, the Government action when Parliament meets, and the general procedure of the doctors were strictly accurate, though much may happen "unofficially," and is, therefore, not officially recognized.

A belief seems to be gaining ground that Mr. Lloyd-George will attempt some compromise and that our average rate of 7/6 if offered with some extras might be accepted. But the grounds for this belief are not very substantial and perhaps may be regarded as mere rumors, or even only as feelers put forward by the Government with the hope of entrapping the profession.

Steps are being taken in many places by committees under the act to carry out its provisions as though the profession would consent to them. This is especially the case in regard to sanatorium benefit. In London a temporary subcommittee has been appointed for each metropolitan borough. The Borough Councils have all consented to their Medical Officers of Health acting on these subcommittees, and have granted the use of their offices for giving information. It is thought that these committees will eventually merge into the district committees, which must be appointed for the boroughs as well as for the cities of London and Westminster. As far as these bodies are concerned there seems no likelihood of delay in organizing all duties devolved upon them by the act. In some instances insured persons have already been sent to a sanatorium or given dispensary or domiciliary treatment.

At a meeting of practitioners on the 20th inst. at Lancaster it was resolved to resign all contract practice appointments in accordance with the policy of the British Medical Association on the Insurance Act. Further than this the meeting resolved to call in consultation only those who are pledged to that policy. This is certainly a strong measure, but it is very likely to be put in force in many localities. Nor is it only the British Medical Association's policy for other organizations or specially formed committees are adopting much the same decisions or agreements, though with slight variations according to local conditions.

The medical staff of the Lancaster Hospital, with one exception, have informed the management that they cannot undertake the treatment there or in other voluntary charities of persons insured under the act. From Dundee in the north to Bournemouth on the south coast come similar reports of unanimity or overwhelming majorities, and only dissentients enough to show the practical union of the profession on the subject.

Some education authorities are withdrawing their provisions which deal with the pay of teachers during sickness on the ground that the Insurance Act compels them to contribute. At Heaton and Isleworth a resolution to discontinue sick pay has caused a petition against it signed by one hundred and fifty-two certificated teachers, who allege that the act was not intended to extend to them and that it is a breach of faith, as it varies the contracts under which they have been working.

The views on the racial effect of tubercle put forward by C. E. W. and mentioned in my last

have naturally called forth vigorous protests; some of them challenge the medical profession not to let them pass without repudiation. Several say immunity can be produced artificially and, therefore, it is not necessary to wait for thousands of years while nature carries on her slow process. Some regard the sanatorium as an agent for raising immunity, but this can only be to a trifling extent. Tuberculin treatment is much more active in this sense and immune substance (the I. K.) enormously greater than that. Against this it is urged that the stamping out of smallpox is but raising immunity artificially by vaccination, and where this is compulsory the disease has disappeared. It is hardly to be expected that preventive medicine alone can exclude an infectious disease from any community, and if it could the first intrusion of the germs would offer a pure soil for the rapid spread of that disease. Many think that the gist of C. E. W. was to advocate waiting nature's slow method and that to propose scientific rapid methods is an unanswerable reply. But the logic of his statement might rather point to the lethal chamber.

In the antituberculosis exhibition which I mentioned had been opened, prominent objects are various forms of shelters erected in the garden of the house of the Medical Officer of Health by which the exhibition has been organized. One of these revolves on a circular rail. The doors and windows are all removable so as to secure such ventilation as may be desired in any case. In another pattern the ventilation is regulated by Venetian blind. Among other exhibits are aspirators of different forms for antiseptic and other inhalations as well as for disinfecting; milk sterilizers and milk humanizers; many milk and other food preparations; drugs, disinfectants; soaps; instruments for examining the blood and other fluids; a special form of bedding which it is said is perfectly damp resisting and will stand steam disinfection without detriment.

A prominent place is given to a dust collector, not unlike that which one has seen in Switzerland, and the general adoption of which would be a boon in London. Here the primitive system with the cart into which the dust and rubbish is shot from the house bins is a constant offense. The plan proposed only requires the householder to have a tin contrived to fit a groove of the cart along which it can be slid. Then a trap door opens and at the same moment opens the bottom of the tin, emptying it. Then the sliding the reverse way automatically restores the previous position, the tin being empty. The cart can just as easily discharge its contents into a destructor or rubbish chute. Our local authorities might well adopt the plan and their sanitary advisers will perhaps suggest it.

At the concluding meeting of the Hospitals Association at Birmingham Mr. Gilbert Barling, senior surgeon of the General Hospital, urged that there should be one body and that the managing committee be responsible for administration. Colonel Roxburgh of Glasgow Infirmary supported this, but he would not interfere with the medical department. So agreed Mr. Campbell of Dumfries Royal Infirmary, and Mr. West, chairman of St. George's Hospital, London, who as others hoped the voluntary system would be maintained. Dr. Cureton (Salop Infirmary) was of the same opinion and thought they must be very careful about allowing inspection or they might find themselves taken over by the Government. They must maintain the voluntary system, not only of the hospital but of the sanatorium also. Mr. Denvers Powis, Councillor of King Edward's Fund, read a paper arguing that the life of the voluntary system was local management. Once let a central authority touch details and the system was taken away and he would never be associated further with it. Responsibility must be undivided. Medical work was separate. But there is a wide stretch of country between the physician's prescription and the kitchen maid's evening out.

The Royal Sanitary Institute has established a special examination for candidates for the post of smoke inspector. Certificates are to be awarded and forty sanitary authorities have agreed to act as examiners. The first examination will be held in Manchester in April, 1913.

Next week will be occupied by the Eighth Medical Exhibition, organized like its predecessors, and the Chemists' Exhibitions by the staff of the *British and Colonial Druggist.*

The Corporation of St. Helen's has obtained parliamentary power to detain persons suffering from phthisis when proper precautions are not or cannot be taken to prevent the spread of the infection of tuberculosis. Under their act on September 23 a man living in a small house with two children and five adults who refused to go to the workhouse was ordered by the magistrates, on the representation of the Medical Officer of Health, to be detained for three months.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

NEW CASES OF PLAGUE IN MANILA—MODE OF INFECTION A MYSTERY—STATUS LYMPHATICUS LIABLE TO BE MISTAKEN FOR PLAGUE—MANILA MEDICAL SOCIETY—PERSONAL.

MANILA, P. I., August 14, 1912.

As has been stated in a former letter, there were two cases of bubonic plague in the city of Manila during June, one on June 17 and the other on June 26. There was a complete absence of the disease from the Philippines during the entire month of July, except one case at Iloilo, which is a port which, heretofore, has always remained free from this disease. On August 19 two additional cases were discovered in Manila. These occurred in the persons of two boys who were students at the Ateneo College of Manila and lived at 27 and 37 Calle Villalobos, respectively. The history of the cases does not show that the boys were companions, either inside or outside of the school, or that they had anything more in common than what is stated above. Both were typical cases of bubonic plague, and resulted fatally. A thorough investigation was made of the houses in which they lived, and of the vicinity, but no dead rats were discovered. Many rats have been caught in the neighborhood of the houses since the deaths took place, but none have shown any evidence of plague. On August 11 another case of plague was discovered in the person of a Chinaman, a barber, who lived and worked at 417 Calle Poblete. This house is within half a block of where the first victim worked, who died on June 17, and who was the one who had the first case discovered in Manila in six years. No dead rats have been found in the vicinity, and since the death of the first case, several thousand have been caught in this neighborhood, but none of them have shown

any evidence of plague infection. An inspection of the premises in which the last case occurred showed that next door to the place in which the man worked was used as a warehouse by an importing firm which deals in imports from China and Japan. For instance, there were large numbers of crates which contained lamp chimneys around which straw was packed; great numbers of baskets of garlic, onions, and other dried vegetables, all of which furnish most excellent harboring places for rats, and it is assumed that possibly some plague infected rats may have been introduced into Manila from China or Japan in this way. There have been over 4000 rats caught in Manila since the first cases occurred, and all of them have been carefully examined by laboratory methods, and, so far, none of them have been found to be plague infected. Rats which show glandular enlargements or other pathological evidences that might be taken for plague, have the very delicate test applied of having suspected material rubbed upon the shaved surfaces of guinea-pigs with the view to infecting them, but, so far, none of the guinea-pigs so treated have contracted plague.

In view of the foregoing it is evident that, so far, no specific evidence has been adduced as to the manner in which plague has been introduced in Manila. It is noteworthy that all the cases occurred in permanent residents of the city, and, with the possible exception of the Chinaman, none of the victims had been in contact with persons who ordinarily make visits to China or Japan, or who come from those countries.

In connection with the plague work, it has been customary to transfer to the hospitals all cases suspicious of plague, and to make daily examinations of all deaths in the city, in order to be certain that no plague cases are being overlooked. In this way several cases of status lymphaticus have already been encountered, and it is interesting to observe that during the acute stage of this disease it is difficult to distinguish it, clinically, from plague. In addition to the cases of status lymphaticus there have also been a number of cases that have been diagnosed as glandular fever. Repeated laboratory examinations of these cases have failed to reveal any plague bacilli, and all of them have recovered so far as the fever was concerned, but the glandular enlargements have persisted. The cases generally give a history of several days' illness with fever, general malaise, loss of appetite, and then the femoral glands begin to swell upon one side, soon resulting in a typical bubo; the other limb usually becomes similarly involved from 10 to 24 hours later. This is followed by axillary, cervical, and often epitrochlear enlargements. The whole process lasts about seven days when the fever gradually disappears and, in a few days more, the patient is ready to leave the hospital.

The regular monthly meeting of the Manila Medical Society took place in the upper amphitheatre of the College of Medicine and Surgery, at 8.30 P.M., August 5, 1912. The meeting was devoted exclusively to the exhibition of *x*-ray plates taken of various cases treated at the Philippine General Hospital, and presented nothing out of the ordinary or of unusual interest.

Drs. Hardee and Cox, graduates of 1912 from the Jefferson Medical College, and Dr. Diller, a 1912 graduate from the University of Pennsylvania, have arrived in Manila, and have been appointed internes in the Philippine General Hospital.

FIFTEENTH INTERNATIONAL CONGRESS ON HYGIENE AND DEMOGRAPHY.

(Special Report to the MEDICAL RECORD.)

SANITATION OF ROADBEDS, STATIONS, AND REPAIR CAMPS—SANITARY SUPERVISION OF MERCHANDISE IN TRANSPORTATION—MILK DISTRIBUTION—INDUSTRIAL ANTHRAX—HOOKWORM DISEASE IN PORTO RICO AND THE UNITED STATES—OCCUPATIONAL BRASS POISONING—INDUSTRIAL MERCURIAL POISONING—INDUSTRIAL PLUMBISM—OCCUPATIONAL DISEASES IN NEW YORK—LEGAL PROTECTION FOR WORKERS—MUNICIPAL VITAL STATISTICS—INFANT MORTALITY IN THE UNITED STATES—MORTALITY OF BREAST-FED AND BOTTLE-FED INFANTS—INFANT MORTALITY IN NEW YORK—CONTROL OF MALARIA—PREVENTION AND SPREAD OF YELLOW FEVER—PROPHYLAXIS OF SLEEPING SICKNESS—STRONGYLOIDES AND ANKYLOSTOMUM INFECTIONS.

"The Sanitation of Roadbeds and Stations" was discussed by the Section on Hygiene and Transportation. Professor William T. Sedgwick of the Massachusetts Institute of Technology, Boston, Mass., and Dr. Eugene R. Kelley, Health Commissioner of the State of Washington, read papers and Dr. H. Taylor Cronk of New York described and illustrated an apparatus which could be attached to the toilet and washstand of a car which would collect all excreta, separate the liquid from the solid, disinfect and retain them without the return of noxious odors to the toilet room. The device would cause but little change in the present method of the construction of cars and would detract nothing from their appearance. Dr. T. D. Tuttle, State Board of Health of Montana, spoke of the "Sanitation of Railroad Construction and Repair Camps," and after calling attention to the various measures which were necessary to secure proper conditions in such camps said that at a meeting of representatives of Boards of Health, Railroad Commissioners, and Railroad Operative Departments, held in Helena in March, 1912, a set of regulations relative to railroad camps were drafted. These regulations had been adopted by the State Board of Health of Montana, and would go into effect October 1, 1912, and he believed that if these regulations were strictly enforced, much of the disease resulting from these camps would be eliminated from the State. Dr. Thomas R. Crowder of Chicago presented a study on the "Ventilation of Sleeping Cars" and described the exhaust methods used in the modern steel car by which the air supplies to the lower berth are from 1400 to 2200 cubic feet per hour. He illustrated the various findings by tables and charts.

"The Sanitary Supervision of Merchandise in Transportation" was also discussed at this session, Dr. Robert M. Chapin, Bureau of Animal Industry, Department of Agriculture, Washington, D. C., giving an illustrated talk on the subject. After describing the methods which are in actual use in the various modes of transportation he said that betterment of conditions must be obtained through (1) development of intelligent public sentiment; (2) commercial inducements; (3) efficient inspection service. All three are closely interdependent, but the maintenance of expert and efficient inspection service is the final agency through which results can be accomplished. Dr. John R. Williams of Rochester, N. Y., gave an illustrated talk on the "Economic Problems of Milk Distribution in Their Relation to

the Public Health." He emphasized the point that there could be no general improvement in the public milk supply if the industries associated therewith were not established on a sound business basis; consequently he had studied the economic side of the question. He found that farmers were making milk on land near cities too valuable for the purpose, and experiment had shown that milk could be delivered more efficiently than is now being done at about one-fourth the cost of present distribution.

In the Section on Hygiene of Occupation, Dr. E. W. Hope, Medical Officer of Health, City and Port of Liverpool, Prof. of Hygiene, Liverpool University, and Dr. W. Hanna, Assistant Medical Officer, Liverpool, England, presented a paper on the "Incidence of Industrial Anthrax in Liverpool." They stated that the number of cases of anthrax arising in association with the working in important products was 60, covering a period of about eight years. Thirty-six of these were dock laborers and carters engaged in the discharging of cargoes of ships in the docks, but a large proportion of these cases were infected during the loading or the carting of hides. Six persons contracted infection during the handling of horsehair in hair factories, while 13 contracted the disease during the handling of wools. Dr. Bailey K. Ashford, Major, Medical Corps, U. S. Army, San Juan, Porto Rico, presented a paper on the "Economic Aspects of Hookworm Disease in Porto Rico" and told of the part taken by the hookworm in degrading coffee, fifteen years ago the chief product, to its present condition. Hookworm disease, among other factors, is still preventing the coffee industry from attaining the rich development of the sugar and tobacco industries. There were about 300,000 laborers ill with the disease and it was a very significant fact that a worm-sick laborer could usually be transformed into a healthy man for sixty cents. Prof. C. W. Stiles, Public Health Service, Washington, D. C., told of the "Economic Aspects of Hookworm Disease in the United States." He presented two North Carolina boys, 14 and 17 years old, and said that the mental tests given them by the Binet system showed that, as the result of the hookworm disease, these boys were, so far as their mental development was concerned, only 9 years old. Hookworm disease was a serious economic problem confronting the United States because it reduces the mental efficiency of its victims.

Dr. Emery R. Hayhurst, College of Medicine of the University of Illinois, Chicago, read a paper on "Occupational Brass Poisoning and Brass-Founder's Ague," the latter being an acute malaria-like affection, each attack of very brief duration, and due to the inhalation of fumes arising from molten brass. There is no antidote for this so-called ague, only prophylaxis. Dr. Frank E. Tylecote, Physician to the Salford Royal Hospital and Withington Union Hospitals, Manchester, England, presented a paper on "Industrial Mercurial Poisoning," basing it on 20 cases. The symptom for which the hatters invariably come under notice is the tremor, first seen in the arms and hands. Blackening of the teeth is the main condition noted in the mouth. Dr. Ludwig Teleky, Privat-Docent, Social Medecine, University of Vienna, Austria, presented a paper on the "Dangers of the Use of Mercury in the Industries," in which he described three forms of this poisoning, (1) the subacute; (2) the wholly chronic, and (3) that form in which gingivitis and tremor are noted. The acute form with serious diarrhea hardly ever appears in Austria as industrial poisoning; the subacute form is met with among fire-gilders, and also in Idria; the chronic form is found in well established hat factories. In Austria, Germany, England, and France the mercury mirror has been completely superseded by the silver mirror.

"Industrial Plumbism" was another subject under discussion and many facts of great interest were brought forth. Dr. Alice Hamilton, Special Investigator, U. S. Bureau of Labor, Chicago, said that anilin dyes are beginning to supplant chromate of lead in textiles, wall-papers, artificial flowers, and paints; cut glass is usually finished with acid instead of lead powder; the sulphate of lead has largely taken the place of the basic carbonate in the manufacture of rubber, and is used more and more as a substitute for white lead in the manufacture of paints. These substitutions or adulterations may not always be creditable commercially, but they are an advantage to the workman. There is no legislation in the United States, except in Illinois, which obliges the employer to remove poisonous dust or to provide adequate equipment for personal cleanliness. The results of the admirable legislative control in Europe, on the one hand, and the lack of legislative control in the United States, on the other, can be shown by statistics gathered in a few lead trades which have been intensively studied, viz., the making of white and red lead, of pottery, of glazed tiles, and the porcelain enameling of sanitary ware. Dr. Francis D. Patterson, Philadelphia, believes that industrial plumbism is just as much a preventable as it is an occupational disease, and he tells how this prevention can be accomplished. Dr. W. Gilman Thompson of New York considered the "Occupational Diseases in New York," such as (1) metal poisoning, especially by lead, brass, arsenic, phosphorus, chromium and mercury; (2) poisoning by toxic gases, vapors and fumes, especially illuminating gas, wood alcohol, and acid fumes; (3) poisoning by irritant dust and fibers; (4) compressed air illness, including an abstract of 3,692 cases with 20 deaths reported by Dr. F. L. Keays; (5) occupational injuries to the skin; (6) to the nerves; (7) occupational diseases of environmental origin; and (8) miscellaneous occupational hazards. John B. Andrews, Secretary, American Association for Labor Legislation, New York, presented a paper on the "Legal Protection for Workers in Dangerous Trades in the United States." He said that the labor laws for the regulation of hazardous employment in the United States may be briefly summarized as follows: I. Reporting of Industrial Injuries. (1) *Accidents.*—Forty-two States have now enacted laws providing for the reporting of industrial accidents in factories, mines, and railroads. (2) *Diseases.*—During 1911 and 1912, for the first time in America, eight States enacted laws requiring physicians to report all cases of certain diseases of occupation, including anthrax, compressed air illness, and poisoning from lead, phosphorus, arsenic, and mercury or their compounds. II.—Prevention of Industrial Injuries. (1) *Accidents.*—Forty-eight States have laws designed to provide for the installation of safety devices and to protect workmen against industrial accidents. (2) *Diseases.*—General legal regulations in the interest of comfort and health have been adopted as follows: Provisions for protection against: (a) *injurious dusts,* in twenty-two States; (b) *improper lighting,* in twelve States; (c) *poisonous gases, fumes, and vapors,* in fifteen States; (d) *excessive temperature and humidity,* in eleven States; (e) *work in com-*

pressed air, in one State (New York). By an Act of Congress (April 9, 1912) the manufacture of poisonous phosphorus matches is prohibited in the United States after July 1, 1913. III. Insurance against Industrial Accidents. (1) *Accidents.*—Thirteen States have workmen's compensation or accident insurance laws, all of which were enacted during the last two years. (2) *Diseases.*—In the recent development of workmen's compensation and insurance legislation, no provision has yet been made in the United States for insurance against occupational diseases. For many years it has been our shame in the United States that in labor legislation we have lagged behind some of the most progressive countries of Europe. But recently we have made remarkable progress. In a few instances, as in the creation of the Wisconsin Industrial Commission, we have surpassed other countries. Another generation of labor legislation may see America leading the nations of the world.

In the Section on Demography there was a symposium on the "Present Position of Municipal Vital Statistics." Dr. Eugene Würzburgher, Director of the Royal Statistical Office, Dresden, Saxony, spoke for the German Empire. Most of the large German cities carry on statistical work very zealously, as appears in the fact that 42 cities have established statistical offices, and these are concerned not only with demographic statistics but with all fields of administrative statistics. Complete information regarding the collection and tabulation of vital statistics by state officers of the German Empire is found in the supplement to the seventh volume of *Allgemeine Statistischen Archiv.* M. Maurice Sauveur, Director-General of the Administration of the General Statistics of Belgium, Brussels, was to speak for Belgium, but what he offered was read by title. Mr. Frederick L. Hoffman, Statistician, Prudential Insurance Company of America, Newark, N. J., spoke for the United States. The publication of the annual vital statistics of American municipalities is, as a rule, too long delayed and the reports are not available at the time when they would be of most public interest and value. The reports, as a rule, vary so much in essential matters of detail from year to year that they fail to afford an adequate basis for an intelligent study of local mortality in its relation to sanitary efficiency as reflected in the death rates from all causes and specified causes by divisional periods of life. The English plan of uniform annual reports should be followed and a series of standard tables should be adopted, after the manner of the tables required by the Local Government Board. The mortality by age and sex is almost entirely ignored in the annual reports of American boards of health. The true changes in the death rate can only be measured by means of death rates calculated for divisional periods of life and with a due regard to sex, race, and the principal causes of death. The rules of statistical practice, as approved by the American Public Health Association and the Division of Vital Statistics of the Census Office, should prevail as far as practicable to bring about the required uniformity in the tabular presentation of the facts. The Budapest system of death classification is not at present made use of by a single American municipality, although the intrinsic merits of this method are so self-evident that they require no discussion. Most of the health reports of American cities fail to give sufficient consideration to the mortality statistics of previous years. For comparative purposes most of the health reports of American cities are of very limited utility at the present time. The increasing economic and social importance of preventable mortality emphasizes the imperative necessity of accuracy and uniformity, since serious errors may result from the blind acceptance of official, but nevertheless untrustworthy, statistical returns. The mortality from specific causes does not receive the adequate and qualified critical consideration which is essential for the ascertainment of underlying causes of public ill-health due to conditions more or less subject to social control. In infantile mortality statistics, for the first four weeks at least, mention should be made as to the legitimacy and illegitimacy, and whether the child was breast-fed, or nourished by artificial means. Occupational mortality is practically ignored in the health reports of American municipalities; the admirable method employed by the boards of health of Blackburn and Sheffield, England, should be followed. Deaths in public institutions are not, as a rule, redistributed according to the residence of the deceased, and as a result the ward death rates are more or less untrustworthy and frequently seriously misleading. No health reports of large American cities give the mortality by single years of life, although for many purposes such a return would be extremely useful. The graphic illustrations, or charts and diagrams, in American health reports are, as a rule, extremely crude, and from an artistic point of view more of a hindrance than a help in the visualizing of the vital facts of the community to which they refer. Apparently the best method of presenting the statistics of diseases of sanitary importance is the one used for many years by the Superintendent of Health of the City of Providence, R. I., in his annual report, which is a supplementary report on vital statistics. Statistics of births and still-births for American cities are all more or less untrustworthy. The praiseworthy effort of the Census Office to bring about a radical improvement in this respect, and to provide for the American people a tustworthy basis of fact as regards fecundity is deserving of every possible encouragement. In view of the ever-increasing practical importance of eugenics, the data as to births and still-births are to-day of recognized national and even international importance. There is also much urgency for the more accurate reporting of abortions, and the returns should differentiate criminal abortions from those due to natural causes. Statistics of marriage and maternity of some cities are not reported with reasonable attention to matters of detail. Statistics of this kind should show the ages at marriage for both bride and groom, as well as the ages of the contracting parties remarrying, and whether single, widowed, or divorced; such statistics have a practical bearing upon the problem of eugenics. Vital statistics are public property. Registrars of vital statistics hold an exceedingly important position, and for the fulfillment of their responsible duties they are entitled to more ample compensation than is paid in the case of the majority of American cities at the present time. There is, unfortunately, a disposition to have the function of city registrar merely as that of a bookkeeper, instead of the custodian of records of the highest possible legal, medical, and social importance. It is a matter of regret that not a single health report of an American city can be referred to as a suitable model for general acceptance throughout the country. None of the four larger cities (New York, Chicago, Philadelphia, Boston) publishes reports

which conform in essentials to the admirable reports published on the sanitary administration of the County of London, or for most of the large cities of England, Scotland, and many of the British dominions and protectorates throughout the world. At the present time the anual reports of the Medical Officer of Health of the London County Council (Sir Shirley Murphy), supplemented by the annual reports of the Medical Officer of Education (Dr. James Kerr), are the models which suggest themselves to the most earnest seeker after truth and ideals in American health administration.

"Infant Mortality in the United States" was the topic next under discussion and Edward Bunnell Phelps, editor, *The American Underwriter*, New York, told of the "World-Wide Effort to Diminish Infant Mortality—Its Present Status and Its Possibilities." By a series of tabulations and charts tracing the infant mortality of the principal European cities and countries in recent years, he demonstrates a pronounced and, in the main, continuous decrease in the European death-rates, especially in the last decade. Owing to the defective registration and varying accuracy of American statistics, it is impossible to measure the movement of the infant mortality rates of the United States as a whole, or of any large portion of its population. The paper shows that beyond all peradventure at least a material part of the recent decrease in infant mortality is due to the aroused public conscience and resultant widespread public effort to grapple with the problem of preventable infant mortality. Dr. William H. Davis, Vital Statistician, Health Department, Boston, Mass., read a paper on "Statistical Comparison of the Mortality of Breast-Fed and Bottle-Fed Infants." During the siege of Paris, 1870-71, when the milk supply failed, the Parisian women nursed their children and the infant mortality rate fell from 330 to 170 per 1,000 births. A similar fall in the infant mortality rate was seen during the Lancashire cotton famine, when mothers were not at work in the mills. Wherever a large percentage of mothers suckle their children, the infant mortality rate is low. Dr. William H. Guilfoy, Registrar of Records, New York, told of the "Infant Mortality in the City of New York," and stated that in the second largest, the most congested, and probably the most cosmopolitan city in the world, the death rate among infants is not necessarily higher than that of the smaller and less congested cities. The death rate under one year of age per 1,000 births in New York City in 1911 was 112. The rate for London in 1910 was 104. The cosmopolitan character of a city is one of the stumbling blocks in the pathway of the health officials. Ignorance of the customs and language with a deep-rooted adherence to the habits and errors of the fatherland are factors that prevent immediate results. It is interesting to note that representatives of the Association of Life Insurance Presidents are attending most of the sections.

In the Section on Military, Naval, and Tropical (Colonial) Hygiene, a consideration of the Control and Restriction of Malaria was entered into. Prof. Dr. Angelo Celli of the University of Rome, Italy, in a paper which was read by Dr. Attilio M. Caccini of New York, discussed the "Restriction of Malaria." The fight against malaria in Italy started in 1898 in the Roman Campagna; thence it extended to the rest of Italy. Through great periodic attenuations of malaria in the course of 25 centuries there had been in the Roman Campagna four eras of civic development and colonization, which were again disturbed by unexpected recrudescences of the epidemic. It was necessary to enlarge the knowledge of epidemiology of malaria in the light of Ross's theory and to restore the prestige of the old remedy. The least organotropic action is obtained by administering quinine every day or two. Certain outlined studies stirred the Italian antimalarial legislation to adopt State-furnished quinine. The exercise of this function enabled the State to accomplish achievements in the fight against malaria which were notable. Through the State-furnished quinine the mortality from malaria had fallen from 15,000 to 3,500 yearly. Marine-Generalarzt Prof. Dr. Ruge, Kiel, Germany, said that in the fight against malaria one or another method of combating the disease must be emphasized, especially the fight against mosquitos, not only their extermination and that of their larvæ, but also the protection of individuals from their bites. In combating the larvæ, we may resort to petroleum and cover ponds and swamps with it, trim off the edges, remove vegetable matter from ditches and ponds, remove old tin cans that serve as breeding places, in short, we must endeavor to destroy all artificially created breeding places, or introduce therein Notanects, and little fish (*Cirardinum pocciloides*), etc., screen wells, incline roof gutters, if for housekeeping reasons it is necessary to store up water reserves. Regions with malaria parasites immune against quinine are to be specially considered. Dr. Edmond Sergent, Director Pasteur d'Algérie, Mustapha, Algiers, said that ten years of antimalarial work in Algeria had led them to the following conclusions: (1) An isolated person protects himself by daily preventive quininization, by the bed screen, and by avoiding the neighborhood of the reservoir of the virus and the breeding places of anopheles. (2) A collectivity (family, administration, etc.) protects itself by the daily preventive quininization, by collective mechanical protection, by selecting their dwelling place far from the reservoir of the virus and breeding places of the anopheles, and by slight antilarval measures. (3) The State should aim at the modification of the virus reservoir, constituted chiefly by natives. The State must also educate the people and teach antimalarial hygiene, chiefly in the schools.

Dr. J. A. Le Prince, Chief Sanitary Inspector, Ancon, Canal Zone, read a paper on "Recent Progress in Antimalarial Work with Specific Reference to Anopheles Flight as Studied on the Isthmus of Panama," in which he stated that for rapid eradication or control of malaria in the tropics it is essential, first, to determine which anopheles production areas affect the town, village, or settlement, and then to concentrate the antimalaria work upon such places.

Dr. J. H. White, U. S. Public Health Service, spoke of the "Dissemination and Prevention of Yellow Fever and of the Agency of the Mosquito in its Dissemination." The methods employed for destroying the infection were, first, by segregating all the infected mosquitoes and destroying them at leisure; second, the general destruction of all mosquitos, thus preventing any reproduction. Dr. Harald Seidelin, Liverpool, England, presented a paper on the "Nature of Yellow Fever and Its Prevention" and said that his recent experience in Yucatan had strengthened his belief in *Paraplasma flavigenum* as the specific parasite in yellow fever which was transmitted by *Stegomyia fasciata*. In the absence of *Stegomyia* there is no need of quarantine.

M. le Dr. Laveran, Member de l'Académie de Médicine, Paris, France, and M. le Dr. Rhiroux, Médecin des troupes coloniales, Saint Louis, Sénégal, presented a paper on the "Prophylaxis of Sleeping Sickness." Endemic for a long time on many points of the western coast of Africa, from Sénégal to St. Paul de Loanda, sleeping sickness has spread greatly during the last years, in the Belgian Congo, the French Congo, in Uganda, and in German East Africa; the question of the measures to be taken to combat this plague which depopulates entire regions of intertropical Africa claims the urgent attention of hygienists. The sleeping sickness is caused by the *Trypanosoma gambiense*, Dutton, 1902, and spread by the *Glossina palpalis* and possibly by other species of tsetse flies of glossines. In Rhodesia N. E. there exists a form of sleeping sickness of which the agent differs from the ordinary *Trypanosoma gambiense* and which is spread by the *Glossina morsitans*. Glossines alone, among blood-sucking insects, appear to be able to spread sleeping sickness and, as these flies are seen only in intertropical Africa, it is to be hoped that the disease will not spread beyond this area. The sleeping sickness has often been imported, especially in America, and one cannot mention any cases of contagion noticed outside of tsetse areas of Africa. As in the case with malaria, prophylaxis must apply here, on the one hand to the spreading agent, on the other, to those affected. (1) *Measures to destroy the glossines or protect man from their stings:* Glossines multiply in moist ground, protected by thickets from the heat of the sun; therefore methodically clearing the thickets around agglomerations is one of the most useful measures to be taken against glossines. The removal of native villages located on the shores of *Glossinæ palpalis* infested lakes or rivers has been prescribed, often successfully, chiefly in Uganda. The use of bird-lime or latex of certain plants, has given favorable results in the destruction of glossines in Principe Island and in Nyassaland. The mechanical processes of protection which render such great service in the prophylaxis of malaria may also be utilized against glossines. No effective vaccination against human trypanosomiasis is known. No drug is known which may be used preventively, in a continuous way, as is quinine in malaria prophylaxis. (2) *Measures to prevent patients suffering from trypanosomiasis from spreading the disease*: In the areas where sleeping sickness is endemic, camps or villages in which the patients are gathered and submitted to proper treatment should be created. Isolation camps or villages should be installed in places where there are no glossines. To prevent the spread of the disease in areas still unscathed, there should be created inspection stations on the highways, so as to prevent those suffering from the disease to enter these areas. Workingmen passing from one region to another must have health certificates issued within less than a year. The fight against sleeping sickness has already begun in many points of intertropical Africa; in order to coordinate all efforts and render them more effective, it is desirable that an agreement be reached between all interested governments.

Prof. John L. Todd, McGill University, Montreal, Canada, read a paper on the "Prevention of Human Trypanosomiasis" and believes that not enough is known of the disease to permit the assertion of an absolute means of preventing it. A comprehensive consideration of the disease must discuss the host, the parasite, the fly, and the relation of these to one another. Dr. Samuel T. Darling, Ancon, Canal Zone, presented a paper on "Murrina, a Trypanosomal Disease of Horses in Panama and the Means Used in Controlling an Outbreak." This disease is confined to work horses; in no instance was a saddle horse attacked. Drs. F. G. Novy, W. A. Perkins, and R. Chambers, University of Michigan, Ann Arbor, Mich., presented a paper on "Immunization by Means of Living Cultures of Trypanosoma Lewisi," Capt. Edward B. Vedder, Medical Corps, U. S. Army, presented a paper on the "Prevention of Beri-Beri" which was read by Capt. Henry J. Nichols, Medical Corps, U. S. Army, Washington, D. C.

Prof. Dr. F. Fülleborn, Hamburg, Germany, read a paper on the "Method of Infection with Strongyloides and Ankylostomum." In dogs whose trachea or esophagus has been severed a comparatively light infection appeared after a subcutaneus injection with larvæ of strongyloides and askylostomum, while most of the larvæ were excreted from the operative wounds. If these and supplementary experiments confirm on the one hand the views of Loos concerning the migration of ankylostoma larvæ which have penetrated into the body through the skin, they show, on the other hand, that a fraction of the larvæ, although infinitesimal, reach the intestine through the circulation of the blood after having passed the lungs. When strongyloides larvæ are fed directly into the stomach of the dog apparently all perish except those which succeed in penetrating the walls of the stomach. The former return to the stomach by way of the stomach wall, vascular system, right heart, trachea, and esophagus, and give rise to an infection which, however, is insignificant if the trachea of the dogs has been previously severed. Strongyloides can develop into a sexually mature filariform parasite not only in the intestine, but in the trachea as well. Dr. Fülleborn also presented a paper on a "Differential Diagnosis of the Microfiliriae of the Blood" and gave some demonstrations of some "Kinematograms for Instruction in Tropical Medicine." One film showed the cultivation of strongyloides or ankylostomum according to Fülleborn's funnel method, the development of strongyloides in manure and the penetration of the filariform larvæ into the skin of the guinea-pig. A second film showed the larvæ, pupae, and the imagoes of the mosquitos, likewise the preparation of the stomach and the salivary glands of the mosquitos. A third film showed the miracidia of the *Schistosomum hematobium* emerging from their shells.

(*To be continued.*)

Progress of Medical Science.

Boston Medical and Surgical Journal.

October 3, 1912.

1. A Further Study of the Problem of Race Betterment. J. Ewing Mears.
2. A Contribution to the Study of Coccygodynia. C. G. Cumston.
3. Results of the Complement Fixation Test for Gonorrhea at the Massachusetts General Hospital. R. F. O'Neil.

1. **The Problem of Race Betterment.**—J. Ewing Mears presents the following propositions for discussion: (1) The State, in the exercise of its duty as guardian of the privileges and of the rights of its citizens, and, as well, charged with the duty of affording protection against conditions which are harmful to its social integrity, has the right to enact laws which will prevent the perpetuation of criminality and of degeneracy by inhibiting procreation in the confirmed criminal and in the defective subject. (2)

The confirmed criminal and the defective subject may be rightfully regarded as in a state of disease, mental, moral, and physical, and therefore, the legitimate subjects for medical and surgical treatment. (3) Extended experience on the part of competent students of criminology and sociology, confirms the opinion that neither education nor punitive measures are effective in restoring the criminal and defective subject to normal conditions. (4) As heredity is conceded to be an important factor in the perpetuation of criminality and degeneracy, through the power of procreation, the fundamental treatment of these conditions consists in the abrogation of this power. (5) Experience teaches that in many of the criminal and defective subjects inverted or perverted sexual desires and practices are the dominating factors of their disordered conditions. In such subjects remedial and curative results can only be obtained by depriving them, through the chosen surgical procedure, of the sexual power. (6) That the testes and ovary produce an internal secretion which is necessary to the normal functioning of the body tissues has been demonstrated. It is believed that after cord or tube ligature sufficient blood supply, through the collateral circulation which is established, is distributed to these organs to maintain this secretion. (6) Surgical procedures instituted for the prevention of procreation in the confirmed criminal, pervert, degenerate, idiot, imbecile, epileptic and vicious insane should not be regarded as a method of punishment, but as a remedial measure, the sole objects of which are the betterment of the human race, through the arrest of the continually flowing stream of degeneracy and the mental, moral, and physical improvement of the defective subject.

2. Coccygodynia.—C. G. Cumston notes that in considering the differential diagnosis between this and other conditions, the following facts are to be borne in mind. A methodical examination of the coccyx by palpation will eliminate any lesion if none is present. In sacrocoxalgia the pain is distinctly located in the sacroiliac joint and not in the sacrococcygeal articulation. Then again, pressure over both iliac crests awakens the pain in sacrocoxalgia but does not give rise to any in coccygodynia. Neuralgia of the lumbar plexus need not call for one's attention but that of the sacral plexus may give rise to some confusion if a careful exploration is not carried out. The author points out that in the preataxic period of tabes fulgurating pains may occur in the anococcygeal region, but the true nature of the trouble may be detected with the aid of the pupillary symptoms particularly. The neurasthenic woman and her accompanying backache provide a source of error, and in many cases of failure of surgical treatment the coccyx has been removed from this type of subject. The treatment is strictly surgical and if one is dealing with a real case of coccygodynia very excellent results will be obtained by resection of the coccyx in most cases.

2. Sarcoma of Mediastinum.—H. B. Allyn reports two cases of this condition. He states that while tumors may develop either in the anterior or the posterior mediastinum, they are distinctly more frequent in the anterior, the ratio of frequency in the two places being about three to one. Primary malignant tumors are generally of thymic origin. They form a hard, fibrous, generally whitish mass, occupying the anterior mediastinum, adherent to the sternum and adjacent organs. They give rise to general symptoms which most frequently include extreme weakness, often with some cachexia, and to local symptoms depending upon the organs subjected to pressure.

6. Control of Prostitution.—F. Bierhoff believes that the first steps for departments of health to take, if they wish to be considered sincere in their attempts to grapple with the problem of venereal diseases, should be the establishment of a hospital for the proper treatment of patients of both sexes, and of all ages, afflicted with venereal diseases, who may not be able to find accommodation in other hospitals; the passage of enforceable laws to compel every hospital that receives financial support out of city funds, to accept and treat cases of venereal diseases; to bring about the passage of enforceable laws providing for the medical examination of all individuals, men as well as women, arrested on the charge of vagrancy (which includes prostitution, solicitation, pimping, etc.), and to provide for the compulsory hospital treatment of individuals of this class found to be infected with venereal diseases. When this has been done, one might proceed to the reporting of all cases of venereal diseases, but without names.

1. Salvarsan in Syphilis.—J. H. Fordyce states that the efficiency of salvarsan bears a direct relation to the age of the infection. In the early stage three or four doses supplemented by mercury will in many cases cure the disease in from six months to a year. The florid stage requires more intensive treatment; five or six doses followed by several mercurial courses are necessary. In some forms of syphilis of the nervous system the effects of salvarsan are more satisfactory than mercury and potassium iodide. In malignant syphilis, when mercury has been given over a long period continuously without changing the clinical manifestations or the blood reaction, not infrequently all of the manifestations disappear after one or two doses of the drug. These patients probably develop more or less immunity to mercury, or their strains of spirochetes are more amenable to arsenic treatment. A reaction uninfluenced by a long course of mercury may be changed by one or two injections of salvarsan. In other words, a com-

bination of salvarsan and mercury is more efficient in changing the blood reaction than either alone.

3. Anaphylaxis to Salvarsan.—H. F. Swift has observed that after repeated injections of salvarsan, certain patients show symptoms of a respiratory and vasomotor nature like those seen in anaphylaxis, and in one of the author's cases there occurred a toxic erythema. Guinea-pigs which have been sensitized by the injection of a mixture of guinea-pig serum and salvarsan, and have been reinjected, after a suitable time, with the same mixture, show symptoms like those seen in anaphylactic shock. The mixture acts like a foreign proteid.

7. The Intensive Treatment of Syphilis.—By H. T. Swift and A. W. M. Ellis. (See MEDICAL RECORD, Vol. 81, page 1166.)

11. Secondary Syphilitic Meningitis.—A. W. M. Ellis notes that this condition may occur early in the course of syphilis. It may be latent, causing no obtrusive symptoms, over long periods. It is a more frequent complication than is commonly considered. The so-called nerve recurrences after salvarsan are examples of such a meningitis. In most cases the infection of the nervous system has probably already occurred before the institution of treatment. Syphilitic meningitis represents the development of the disease in a region notoriously difficult to reach with curative agents. The belief that salvarsan predisposes in any way to the development of disease of the nervous system has not yet been confirmed.

2. The Etiology of Paresis.—W. F. Robertson believes that syphilis merely predisposes to the development of paresis, which is in reality caused by chronic infection with a microorganism which is stated to be an attenuated form of the Klebs-Löffler bacillus. The author applies the name "*Bacillus paralyticans*" to this member of the diphtheroid group. If hemoglobin agar is used as the culture medium, it can be shown that the *Bacillus paralyticans* is constantly present in the genitourinary tract and the nasal mucosa of the general paralytic. In tabes dorsalis there is always in the early stages an infection of the genitourinary tract by a similar microorganism; in the later stages this bacillus may be entirely displaced by a coliform one. The nasal infection in general paralysis can be traced along the lymphatics, through the base of the skull, to the intracranial lymphatic system, and a culture of the bacillus can be obtained from the cerebrospinal fluid in a considerable, though certainly not a very large proportion of cases. The intraspinal injection of living cultures of the *Bacillus paralyticans* in rabbits has produced lesions in the cord identical with those that occur in the brain of the general paralytic. In tabes dorsalis, especially in early cases, the results of vaccine treatment have in many instances been highly satisfactory. The gait has become steadier, pain has been relieved, and the patient's general health has improved. It has only been in very advanced cases, and in the thin, neurasthenic type of patient, that the results have been in the least discouraging. In general paralysis, on the other hand, the most that the author can claim is that in a few cases there has apparently been some retardation of the rate of progress of the malady.

7. Vaccine Treatment of Respiratory Diseases.—T. and G. Bodley Scott have found that the treatment of the purely nervous type of spasmodic asthma by vaccines is not very encouraging. There are so many exciting causes outside the respiratory tract that this is only what one would expect; still, in these cases such a chronic catarrhal condition, with expectoration and emphysema, often gradually comes on that the accompanying phenomena of the original disease may be much relieved and life with comparative health may be prolonged. The great success of the treatment lies in the cases of bronchial catarrh and dyspnea that so often follow influenza, pneumonia, and acute bronchitis.

1. Carcinoma of the Colon.—V. Z. Cope calls attention to the fact that in this condition there is no constant, ordered sequence of symptoms, for any one of a large number may be the first noticed. Constipation, diarrhea, vomiting, pain, a tumor, increasing distention of the abdomen—one or several of these may herald the condition. A point to be laid stress upon is that the condition may be latent, and an attack of acute or subacute obstruction may be the first serious symptom to which attention is drawn. This is especially true of the scirrhous type. It is quite common to meet with cases which furnish a history of only a few weeks' constipation in which the growth as seen at operation certainly must have been growing for a much longer period. It is therefore all the more necessary to pay attention to slight symptoms of bowel trouble, so that, if possible, one may detect any morbid condition in the earliest stages.

2. Indications for Operation in Acute Appendicitis.—W. G. Richardson lays down the following rules that should guide one in deciding whether or not to operate in a given case of appendicitis: If all the symptoms have not improved, or if any one of them has become more marked, the inflammation is not subsiding, and it is necessary to remove the appendix. (1) The patient may look well, the local tenderness may be slight, the temperature may be normal, but if the pulse-rate continues to rise (a fact to be ascertained by repeated countings) the appendix should be removed. (2) The patient may look well, the local tenderness may be slight, the pulse-rate may be slow, but if the temperature has risen the appendix should be removed. (3) The patient may look well and the temperature and pulse may both be normal, but if the local tenderness has increased the appendix should be removed. (4) The local tenderness may be slight, the temperature and pulse may both be normal, but if the patient looks worse the appendix should be removed.

Sterilization of Skin by Alcoholic Solution of Mercury Bichloride.—C. Clarke states that bichloride of mercury in methyl alcohol (strength 1 in 500) is a more powerful antiseptic than tincture of iodine, and has practically none of the latter's disadvantages. It can be painted

over parts of the body where the integument is delicate, as over the penis, scrotum, anus, etc., and causes only a slight burning sensation when first applied. It can be freely used, and no local inflammation results as long as the alcohol is allowed to evaporate. A small superficial burn, however, is caused by the solution if a swab or towel soaked with it is left in contact with the patient's skin during the operation. This untoward result can easily be avoided. The solution does not stain clothing or towels, and no irritating vapor is given off as it dries on the skin. As an antiseptic the bichloride solution is very efficient, and no preparatory dressing of the skin is required before the operation.

Epidemiology of Diphtheria and the Warfare Against the Disease.—Von Drigalski in an address before a recent Health Congress, said in part, that since Loeffler made his great discovery, no real systematic crusade based upon the latter has been undertaken. Something has been done in a limited field. Thus in the German Army, the carrying out in practice of all theoretic requirements has been followed by brilliant results. The proper use of antitoxin furnishes the chief weapon in the control of the disease which no longer kills in a wholesale manner: this, despite the fact that during the past six years the long expected recrudescence of a severe type of the malady has occurred. This recrudescence gives us the cue to attack the disease with renewed vigor in the hope of exterminating it. At its worst to-day it has about the mortality of typhoid, and there is seen a definite relationship between increased morbidity and increased mortality. The first step in the warfare is correct diagnosis. Neisser's method is regarded as satisfactory and the inventor himself seems to be the most severe critic of it. When this method fails it is on the safe side for the public, *i.e.* the positive identification is at fault, not the negative. Masked diphtheria (masked as simple angina) and the healthy carrier furnish two problems which cannot be ignored or even minimized in a crusade. The habitat of the bacillus furnishes a moot point, and among those who regard it as ubiquitous is von Behring himself. As a matter of statecraft the author opposes the giving of antitoxin in advance of a bacteriological diagnosis. Should anything go wrong—an anaphylaxis develop for example—ammunition is furnished to the medical sciolist. In a close community of 185,000 inhabitants, the author despite the recrudescence of the disease in a severe form, is able to show good results from a campaign directed against the chief factors in dissemination. In 1906, the first year of the exacerbation, there were 1,302 cases. The following year the number had risen to 1,550. The morbidity then exhibited a progressive annual decline (1,283, 920, 822, 578). The scarlatina curve for the same period shows a maximum just at the time when the diphtheria morbidity was rapidly receding. This appears to furnish one of the very best evidences that the latter affection was brought under relative control. Comparison of diphtheria with measles and influenza gives an analogous result. Naturally the management of the school child was an all-important factor in the crusade.

Familial Hemolytic Icterus.—Mosse states that this affection was first recognized by Minkowski in 1900. How it could have escaped the attention of the older clinicians is a puzzle. No doubt it was recognized as an individual finding at a much earlier period. Thus in 1856 Henoch mentions the case of a young girl with splenic tumor and a green tint. The new malady has received a good deal of attention in France and has been recorded in England and Italy. The author is able to add two cases to the recorded material. As becomes a familial affection, the condition once developed is eminently chronic. The first patient seen was a man aged 33, with the picture of anemia, icterus and splenic tumor. The duration was at least ten years. The anemia and jaundice were evidently due to a constitutional hemolysis. The latter was evidently either primary or the result of a congenital anomaly of the spleen. Suspecting the presence of a familial affection the author at once investigated the patient's kindred. The father, dead at 52, had suffered with the same affection. The mother and two very young children were normal. Two of the older children were examined, and one of these, a girl aged 19, showed the disease. There were several others not accessible for personal investigation, but it was learned through a medical man in the residence of one of the brothers, that the latter had the affection in a pronounced form. Hence there were at least four cases in a family comprising ten individuals.

Modern Dietetics of Renal Affections.—Kakowski, a Russian, sums up this subject as follows: In acute nephritis after two days on alkalinized water only boiled milk in increasing quantities up to two liters daily, in small, often repeated portions. Upon the tenth day cream and butter may be added. During the third week there should be added little by little sugar, rice, white bread, tea—in general carbohydrates. In subacute nephritis, to the same daily menu add harmless fruits and vegetables and two or three eggs. In chronic parenchymatous nephritis the protein should be kept down to 70 gms. daily. Cereals, bland fruits and vegetables, fruit juices, milk, butter, bacon and eggs may be used without fear. The protein should be furnished by eggs, fowl, and the other meats, provided they agree. The greatest stress is laid by the author on fresh foods. Under no circumstances would he give preserves, pickles, sausage meats, smoked meats, game, meat extracts, relishes, alcohol, cheese, etc. In contracting kidneys the chief dietetic indication is not to overload the circulatory system with liquids. All food not fresh and all pungent substances are forbidden. Patients with all forms of chronic nephritis must receive their 2,500 daily calories just as should healthy individuals moderately active.

Münchener medizinische Wochenschrift.

September 17, 1912.

Action of Febrile States on Metaluetic Affections of the Central Nervous System.—Friedlander states that this subject possesses much historical interest, as it involves the treatment of all psychoses by pyretogenous substances. The use of the seton in the scalp in the management of insanity no doubt set up fever in some cases, as did ordinary cowpox vaccination when used for the same purpose. One Rosenblum inoculated 22 subjects with recurrent fever matter, and claimed eight cures and eight improvements. The date and place of this occurrence as well as the maladies with which the 22 suffered are not stated. Wagner von Jauregg occupied himself for years with pyretogenous substances in this connection, beginning in 1887, and either used or contemplated the use of a number of animal viruses, including those of recurrent fever, malaria, erysipelas, and tuberculin, the last named having been tested in 1895. Since that period other substances have been tested—toxalbumoses, dead cultures, of *B. pyocyaneus*, *B. coli*, etc. Most recently Wagner and Pilez have been using tuberculin in association with mercurials on their insane, chiefly paretics. The present author began to study this subject statistically beginning in 1897. He analyzed all published records of typhoid in the insane (including typhus) as far back as 1813, and found a greater proportion of permanently recovered cases than after any other similar accident. This fact of the curability of psychoses by fever was known to Hippocrates. The idea then came near of using the dead cultures of Eberth's bacillus, but these could not be made to

induce fever, nor could any preparation of this origin be made to bring about the desired results. The author was therefore obliged to depend on tuberculin, which he has used systematically on paresis and taboparesis. Wagner's addition of mercurial inunctions was also practised to some extent, but it was known to act unfavorably in certain cases, and the author preferred to alternate it with tuberculin. In two cases of taboparesis the fever treatment caused the stiff pupils to react, and one patient recovered sufficiently to resume his occupation.

Pituitrin Therapy in Peritonitis.—Klotz refers to the vascular paralysis, especially in the splanchnic area, which is attendant upon peritonitis. Heart failure is secondary to this condition. The resulting fall of blood pressure and paralytic ileus are of such character that pituitrin seems to be the logical indication. Still another reason for its exhibition is the ischuria. The author has tested the drug in twenty cases of peritonitis, all of which have been reported elsewhere. While some desperate cases seem to have been saved the author's only inference is that the experience is sufficiently encouraging for an extensive trial. The cases most suitable are those of postoperative peritonitis where drainage is possible and other local measures can be carried out. As soon as the affection develops the abdomen should be reopened, the peritoneum irrigated and drained and pituitrin injected into the veins. Pituitrin acts opposite to hormonal, one of its competitors in paralytic ileus, in that it tends to raise instead of lower the blood pressure. The latter attribute contraindicates hormonal in peritonitis.

Circumcision Treatment of Carbuncle.—Heddaeus refers to an article by Knoke on the circumcision treatment of phlegmons of the upper extremities and has followed the same technique in the case of a severe carbuncle of the neck. The operation at once limits the local spread of the infection, while the mass naturally sloughs more rapidly. The sloughing process required a long time and the muscles of the neck were laid bare, but patient was apparently no longer in danger of sepis. Collargol was injected to encourage leucocytosis. After recovery seemed to be assured acute sepsis set in, yielding apparently to collargol. But as the patient was an advanced diabetic he passed into a state of acidosis and coma. After transient improvement from intravenous infusion with sodium solution death occurred. The author believes that circumcision is the logical treatment for rapidly spreading phlegmons, carbuncles, and malignant pustules. The spread of the infection is evidently chiefly lateral. The author would not attempt incision of the mass, but a system of radiating incisions into it with iodine applied to seal up the divided vessels and lymphatics of the periphery should probably be practised.

Deutsche medizinische Wochenschrift.

September 19, 1912.

Cultivation and Successful Inoculation (in Apes) of the Bacillus Lepræ.—Reenstjerna relates his results as follows: From leprous material of various origin he was able to cultivate through four generations acid-fast bacilli resebling throughout the *B. lepræ*. A culture prepared from leprous blood he inoculated into a monkey and caused a temporary macular eruption, the bacilli surviving in the tissues. Along with acid-fast bacilli others could be cultivated and an injection of a culture of the latter caused an eruption akin to leprous pemphigus, suggesting a phenomenon due to mixed infection. A culture of still another non-acid-fast bacterium caused the production of a violet-colored macule, and at the same time contractures in most of the joints. The conclusion from these finds is that the lepra exciters represent a high degree of polymorphism. We can no longer associate them with exclusive acid-fast properties. In addition to forms of bacilli, cocci are also present; and the author believes that these varied forms are not mixtures but offshoots from a common stock. Tubercle bacilli are now believed to show similar mutation forms.

New Method of Treating Asthma.—Weiss refers to that type of asthma in which relief is obtained only by hypodermics of morphia. He is inclined to look on paroxysms of this affection as secondary to certain acute blood alterations attended by eosinophilia. These he believes may be due at times to anomalies of hormonic action. He has noticed crises of asthma in subjects presenting diseases of various ductless glands, notably adrenals, hypophysis and the sexual glands. For some time he has been using in routine practice injections of suprarenin and hypophysis extract. Relief is instantaneous. The infundibular lobe of the hypophysis is the portion employed. The injection, which he terms for convenience, asthmolysin, contains 0.0008 g. suprarenin and 0.04 hypophysis extract in ampoules which hold 1.1 c.c. of solution. He has now used his asthmolysin over 3,000 times and has seen but ten failures. The author deduces that the injections correct a glandular insufficiency, although with a powerful drug like suprarenin this hypothesis is not inevitable. It is preferable, however, to inject normal constituents of the body to toxic vegetable alkaloids like morphia, cocain and atropin. Asthmolysin is a safe preparation even in the tenfold greater dose. Despite the descriptive name there is nothing to commercialize, for the formula is published, and there can be no proprietary feature involved. The designation is merely a convenient one for the ampoules.

The Socalled Zeller Method of Treating Cancer.—Wolff refers to methods used for some years past in Czerny's cancer institute and which have recently been described by Zeller. They comprise the internal use of silicates, the local application of caustic pastes and other old, empirical and largely forgotten practices. Wolfff corrects some misstatements of Zeller's. The latter ascribes the introduction of silica into cancer therapy to one "Batty." Wolff traces it back to Schuh in 1854. This surgeon and pathologist reported some remarkable cures from the use of silicious earths. The remedy was introduced independently by an Englishman, Battye, in 1874. Furthermore in America certain mineral waters containing silicates have at times been vaunted in cancer. Zeller in regard to the local caustic use of arsenic goes no further back than Frère Côme and his contemporaries, but Wolff shows that this is one of the oldest known remedies for any disease, having been used for cancer in ancient India and Egypt. In any case, the Côme paste was first mentioned by one Rousselot in 1765, while Gmelin and Gaertner antedated them by several years in a similar combination. The paste in use in Czerny's Institute is actually one devised by Rousselot. Wolff then attacks the alleged cures accomplished by silica and arsenical paste in combination. The chief criticism is that the laity have derived through the lay press unwarranted ideas of the efficacy of the measures employed. Two elements tend to invalidate such an attitude. First, the superficial character of many of the growths, and second, the short observation period.

Nitrogen and Nuclein Metabolism in Gout.—A. Levene and L. Kristeller in their theory of this subject have reached conclusions which harmonize with those of Brugsch and Schittenhelm in so far as they are concerned with the nuclein metabolism. They add, however, the observation that the elimination of nitrogenous substances of protein origin has a protracted character, and that the oxidation of as simple a substance as asparagin proceeds at a subnormal rate. The most striking peculiarity observed in the authors' patient was the very imperfect elimination of ingested urea when the patient was placed on a diet containing only six grams of nitrogen per day, and a much more complete elimination when the diet contained thirteen grams of nitrogen.—*Journal of Experimental Medicine.*

Insurance Medicine.

Uranalysis and the Relation It Bears to the Medical Examiner's Work.—This matter is discussed by Dr. A. T. Gaillard, Philadelphia. Errors in doing uranalysis are very frequently made by medical examiners and Gaillard thinks that the failure to supply accurate information on a very essential and almost elementary medical requirement is due to three causes: 1. Real ignorance of the simple technique or lack of the necessary equipment. 2. Carelessness on the part of the examiner, whose perfunctory work so often fails to demonstrate a reaction for albumin or sugar when one or both are present. 3. The unwarranted assumption on the part of the examiner of the medical directors' duties and prerogatives.

Commenting on the various tests used in uranalysis Gaillard severely criticises Heller's test, giving as his opinion that the simplest, quickest, and most reliable test is the glacial acetic acid, the addition of five to ten drops of a 50 per cent. solution to the upper boiled portion, held, of course, against a dark background for comparison. For all practical purposes this test is sufficient, but, as mucin and nucleo-albumin are also precipitated, it is wise to confirm the reaction by the Purdy or saturated salt solution test. Care should be taken not to add too much of the salt solution. An amount equal to one-sixth of the volume of urine can be gauged pretty accurately by slow addition through a pipette.

As for microscopical analysis and diagnosis, in the opinion of Gaillard, the system employed by most insurance companies is faulty and unscientific in the extreme. From a practical standpoint the following reforms are recommended: 1. The requirement of microscopal examination of the urine when chemical tests reveal albumin, regardless of age, sex, past and present personal or insurance record, or the amount insured for. 2. Microscopical examination of the urine of all applicants aged forty-five and over. 3. The elaboration of some scheme by which this work may be entrusted to a recognized expert for a certain territory, in order to save time and relieve the home office of the congestion which the adoption of such a plan would involve.

The subject of albuminuria, transient or constant, is probably the source of more annoyance to the medical director than any other impairment he is called upon to estimate. Those companies not engaged in sub-standard business usually adopt the arbitrary rule of declining to accept all risks where this impairment is found in two consecutive specimens of urine. This is a deliberate rejection of much good business which might be saved by careful and discriminating selection between the good and the bad. The healthy young athlete with an orthostatic albuminuria is put in the same class with the heavy eating, heavy drinking club man of fifty or over, whose kidneys are seriously affected —both have albumin and both are declined. The young unmarried man applying for insurance before complete recovery from a simple urethritis, whose urine is guilty of a few shreds and a small amount of pus, is classed with the victim of renal abscesses—both show pus in the urine and both are declined.

The same criticism applies to rejections for catarrhal cystitis, or prostatitis, or even mild irritations of the kidney due to an excessive amount of certain urinary salts. In all these conditions the urine will show a small amount of albumin or pus, but the ailment is trifling, is promptly cured under proper treatment, and does not affect the applicant's longevity in the least. But no effort is made to detect the source of the albumin and pus in the urine by microscopical examination, no attempt at a diagnosis is instituted. In the light of our present knowledge it seems amazing that such unscientific methods should be the rule in practically all the insurance companies. Even those supposed to accept sub-standard risks do but little more in their efforts to arrive at an intelligent basis upon which to rate the hazard. A microscopical examination may be made and if granular casts are found the case is usually rejected, but if the findings are practically negative a heavy loading is imposed because of the albumin present. Of course, as Gaillard points out, he is referring to cases in which the age or the applicant's personal history, habits, etc., would ordinarily preclude impairment of the kidneys. Where there is a history of scarlet fever complications degenerative complications may be accounted for, but with a clean record the albuminuria is generally temporary and can be traced to its source. A correct conclusion cannot be reached without the use of this valuable aid to diagnosis.

In short, Gaillard is convinced that the good may be weeded out from the bad by the adoption of scientific principles in the examination of supposedly impaired risks such as those mentioned.

The reverse of the picture is to be found in the second proposition advanced—the requirement of microscopical examination of the urine in all applicants aged forty-five and over. Vital statistics for the past ten years or more show an alarming increase in the mortality from the degenerative diseases and Gaillard thinks that more care should be taken in selecting applicants of this kind who desire to be insured for comparatively small amounts. The largest volume of business is done in small amounts, and yet no microscopical test of urine is required by the various companies for amounts under ten thousand dollars. There is at the present time an immense number of cases of nephritis found in men over forty-five apparently in robust health, and Gaillard emphasizes the point that in such instances the examination of urine is too often not performed in a sufficiently careful and intelligent manner. Fortunately for insurance mortality, most companies now employ to a greater or less extent the sphygmomanometer, and this instrument assists most materially in detecting the arteriosclerosis usually secondary to impairment of the kidney function, even when chemical and microscopical tests as generally performed give negative results. The third proposition, the development of some practical plan by which these results may be accomplished, is hardly within the premise of the medical examiner.

Gaillard is of the opinion that a practical plan would be the selection by each company of one or more capable microscopists in each State and entrust all this work to them. Should there be any doubt as to the fitness of the selection a short tryout at the home office would speedily determine whether the appointment was a good one. There can be no question that all insurance companies before long will pay more serious attention to the vital question of uranalysis, and when this decision is reached it will be a comparatively easy matter to evolve a suitable working plan.—*The Lancet-Clinic,* July 27, 1912.

Book Reviews.

HARELIP AND CLEFT PALATE, with Special Reference to the Operative Treatment and Its Results. By JAMES BERRY, B.S. (Lond.), F.R.C.S., Senior Surgeon to the the Royal Free Hospital, London, Assistant Surgeon to the Alexandra Hospital for Children with Hip Disease, and T. PERCY LEGG, M.S. (Lond.), F.R.C.S., Surgeon to the Royal Free Hospital, London. Assisstant Surgeon to King's College Hospital. Two Hundred and Forty-two Figures and Appendix of Cases of Operation for Cleft Palate. Price $4.00. Philadelphia: P. Blakiston's Sons & Co., 1912.

THE object of the writers of this book has been to describe in full detail the methods that they had found most useful in the treatment of harelip and cleft palate and in the appendix of cases they have endeavored to describe as fully as possible the actual results of their operations for cleft palate. In the work are described the development of the lips and palate, the anatomy and physiology of the lips and palate, the varieties of harelip and cleft palate, the functional results of cleft palate, the treatment of harelip, the secondary operations for harelip, the treatment of cleft palate, secondary operations for cleft palate, and one chapter is devoted to obturators and artificial vela. A very interesting part of the work relates to training in articulation; when once the palate has been completely closed by a successful operation and a good movable soft palate has been given, there is no reason why the patient after careful training should not eventually obtain perfect speech. The child who has suffered from a cleft pal te has never elevated the soft palate, and even after a successful operation this can only be accomplished by skilful training; it will not come without. The volume is replete with drawings, diagrams, and photographs, and is one of the best books which treat of harelip and cleft palate.

THE PHYSIOLOGY OF FAITH AND FEAR, or the Mind in Health and Disease. By WILLIAM S. SADLER, M.D., Professor of Physiological Therapeutics, the Post-Graduate Medical School of Chicago; Director of the Chicago Institute of Physiological Therapeutics; Member of the Illinois State Medical Society, the American Medical Association, the American Association for the Advancement of Science, etc., etc. Author of "The Science of Living, or the Art of Keeping Well," "The Cause and Cure of Colds." etc. Illustrated. Price $1.50 net. Chicago: A. C. McClurg & Co., 1912.

THIS is a book for the layman; and like most books on medical topics, written in popular style, is calculated both to help and to mislead. To illustrate: Arterial sclerosis is spoken of as due to high blood pressure; and high blood pressure as due to fear and worry; old age as consequent on arterial sclerosis; *ergo,* fear and worry are the causes of old age, and the faith state of mind the preventive. Nothing whatever is said in the book, as far as observed, about the potent physical causes of arterial sclerosis. Is this, to the lay mind, not apt to be misleading? Some of the popular reviews of the book state that the author discusses "not only the rôle the mind plays in healing but the bodily factors as well"; and that "both his positions on psychology and physiology have been indorsed by leading representatives of those sciences." The book itself is "dedicated to all who worry; to the victims of fear, moral despair, and other mental maladies; to those who are seeking to know the truth concerning the power of mind over matter; and also to those mental sufferers who have been deceived and deluded by false systems of mental healing." In the preface it is stated: "The author disclaims all pretensions of being a psychologist"; also, "Our one purpose is to tell the story of how the mind affects the body and its various functions in health and disease; how the fundamental mental states of *faith* and *fear* make for or against health"; "To convince the reader that fear is a generator of mental poisons, and worry a corroding canker—ever tending to destroy the mind and produce disease"; "Faith and its moral attributes, the mental emancipator from the bondage of doubt and mind disease." We hardly know how to classify such a book. But there is much in it to commend it. There is a psychological section whose keynote is faith as "the master key to mental medicine"; a physiological section, devoted to the influence of mental states on the circulation, the secretions, respiration, nutrition, etc., and a section on therapy, with chapters on psychoprophylaxis, the psychology of disease, habit, worry, suggestion, psychic fads and fakes, etc. There are 43 illustrations. The laity will doubtless accept the book as authoritative and find it absorbing in interest. It is free from medical terms and not devoted to any particular cult. The physician, on the other hand, while recognizing its general value in inculcating certain well-known principles, will be inclined to criticise it from a scientific point of view as occasionally misleading.

THE ESSENTIALS OF MORBID HISTOLOGY. For the use of students By ALBERT S. GRÜNBAUM, M.A., M.D., F.R.C.P., D.P.H., Professor of Pathology in the University of Leeds; Examiner in Pathology in the University of London; Examiner in Comparative Pathology in the University of Durham With 22 colored plates and 139 other illustrations. Price $2.00 net. London: Longmans, Green & Co., 1912.

IT is not an easy task to write a book on the essentials of histology, for the successful completion of the problem implies rigid exclusion of much material, and hardly any two teachers would agree as to what should be excluded and what included. As a piece of book-making this volume is admirable; well printed and splendidly illustrated for a book of such relatively low cost, and yet on reading it through one has the feeling that the space taken by the illustrations, not one of which could be dispensed with, has compelled too much clipping of the text. There are also no references to lead the student to further reading, and consequently the book can be regarded as suited only for direct class teaching and as furnishing the minimum requirements for a course, the lecturer himself adding a good deal in the way of collateral information and requiring much consultation of larger texts for moot points and rare conditions. Within its limits, however, the volume is excellent and its contents offer an excellent exposition of the minimum requirements of a course in pathology. The only special criticism which can be offered is that directed against Figure 129, which is much more characteristic of a carcinoma of the kidney than of a so-called hypernephroma, however accurately it may follow some individual section furnished to the artist.

A TEXT-BOOK OF PATHOLOGY FOR STUDENTS OF MEDICINE. By J. GEORGE ADAMI, M.A., M.D., F.R.S., Strathcona Professor of Pathology, McGill University and Advisory Pathologist to the Montreal General and the Royal Victoria Hospitals, Montreal, Canada; Late Fellow of Jesus College, Cambridge, England, and JOHN MCCRAE, M.D., M.R.C.P. (Lond.) Lecturer on Pathology and Clinical Medicine, McGill University, Montreal; Senior Assistant Physician, Royal Victoria Hospital; Sometime Professor of Pathology, University of Vermont; Late Fellow in Biology, University of Toronto, Toronto, Canada. Illustrated with 304 Engravings and 11 colored Plates. Price $5.00. Philadelphia and New York: Lea & Febiger, 1912.

PROFESSOR ADAMI, when he brought out his work on general pathology, in several respects made a new departure. He went from the beaten track in the arrangement of the book in that he began not with a study of the blood and of circulatory disturbances but with a study of the properties of living matter. And this was not the only departure from accustomed lines, for he formulated distinctly original views in developing the conception of the biophore or ultimate molecule of living matter into a theory which is applied to the explanation of growth and even to the complex processes of variation, adaptation, and evolution. In short, Adami's general pathology exhibited features which differentiated it from the ordinary work on pathology and which also won for it much favor. In this new work Adami determined, as in the case of the general pathology, to produce a text-book out of the common. The former work deviated from the lines followed by other writers on pathology, by treating the subject on broader principles, and the present text-book has been conceived with a similar end in view. The first endeavor has been to make clear and intelligible what is known concerning the deeper meaning of morbid states. The chapter on inheritance is excellent, but those chapters dealing with immunity and inflammation are perhaps the best of the book. In the chapter on immunity the various forms of antibodies are considered and the author suggests an addition to Ehrlich's conception of side-chain activities. That part of the work in which inflammation is made the subject is particularly full and lucid. It may be noted that the pathological significance of the internal secretions is considered and the part played by secretion in stimulating the flow of the pancreatic, gastric, and intestinal juices is given the attention its importance demands. The book is well printed and illustrated and should prove as useful as it surely must prove interesting to the student of medicine.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 3, 1912.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

Concerning the Life of a Cell.—Prof. Dr. MAX RUBNER, president of the Permanent International Commission of the Congresses of Hygiene and Demography, Berlin, Germany, gave this, the Wesley M. Carpenter lecture. He recalled that in 1836 Schwann in Berlin and Cagniard Latour simultaneously discovered that yeast was a single-celled organism. The relations of yeast to fermentation was not commonly accepted at that time and a bitter fight was waged on the subject, which resulted in victory for Pasteur, who considered fermentation to be a result of the vital activity of yeast. Yeast presented a cellular biology free from every disturbance by the differentiation of cells, freely accessible to the medium of food, provided with known products of metabolic assimilation, and, in short, with everything that invited to a study. The cells of yeast increased by sprouting and under favorable circumstances with the formation of "Ascospores." The cells were without visible motion of the protoplasm until the first stage of sprouting. In their ripe stage they had a kernel which separated at the sprouting; whether in a mitotic manner or not had not yet been determined. The capability of growth was very considerable. The fermentative matter was composed of hexoses and cane sugar, which was easily decomposed into dextrose and levulose. While the ideas first expressed by Pasteur were still prevalent there were signs of the development of the doctrine of fermentation which led far away from his primary idea. He laid no importance, when making comparative observations of fermentative potentialities, upon the *period* of the effects; he therefore did not exclude completely the fermentative character of the process. The further development of theories of fermentation had destroyed Pasteur's doctrine piece by piece. Fermentation was now considered exclusively to be an enzymatic effect, yet, according to the ecological theory, which had been hinted at by Nägeli, and at the present time affirmed by Worthman, fermentation was now considered to be an arrangement for the protection of the yeast, whereby it could better defend itself in its combats with other microorganisms. From the biological point of view there now existed a wide gap, for one must ask, under these conditions, where was that to be found which must be called the process of life and the nourishment of yeast? To bring about a production of enzymes no great amounts of material were required, but every living substance must have in some manner a metabolic assimilation from which it took the forces required for life. Fermentative cleavage could not be considered as such. If the potential energy of organic matter (such as was not otherwise possible in the case of fermentative effects) was changed into heat, this form of energy was no longer suitable to supply the forces required for the maintenance of life. Generally authorities had abstained from replying to this question. Dr. Rubner stated that these difficulties might be removed without a shadow of doubt. The first question was the exact determination of the rôle of the sugar. If yeast possessed, beside the fermentation of sugar, a metabolic assimilation, this must become known when one compared the heat of cleavage of sugar, based upon the thermochemical calculation of the heat of combustion, with the heat of fermentation when yeast had been planted in sugar. If there existed a special metabolic assimilation of yeast this must also produce heat, and this heat of fermentation must produce not only the heat of cleavage of sugar but also the heat of this specific metabolic assimilation. If energy were lacking this could only have been lost to the growing yeast. In order to make these measurements Dr. Rubner had devised an accurate microcalorimeter and had made numerous measurements of the heat of fermentation under various conditions. He had found a complete agreement between the calculated heat of fermentation of sugar, from the thermochemical figures, with the fermentative values of the decomposition of sugar. No other source of heat could be discovered either in the case of nongrowing yeast, nor yet a diminution of the heat of fermentation during the growth of the cell, with the sole exception of the heat of fermentation of sugar. These results showed the theory of Gautier about the conservation of energy during growth, and the theory of Pringsheim about the specific metabolic assimilation of protein in yeast of no account. As yeast needed energy for its life and its enormous growth allowed one to suppose a considerable consumption of energy, sugar must in part at least form the source of energy of yeast. On the other hand, a partial decomposition of the sugar by the yeast enzymes could not be doubted. Opposed to this was the idea that sugar was split in the yeast only by alcohol. Dr. Rubner had calculated that the amounts of ferment produced from the yeast could not in the remotest manner explain the decomposition of sugar of the living yeast, but that by far the greater portion of sugar was destroyed by the living substance. He called this vital portion the "vital decomposition." He had separated both the fermentative and the vital decomposition quantitatively by making parallel experiments with normal yeast triturated with toluol, that was to say killed. Tuluol did not destroy alcoholic enzymes. He had studied the process of fermentation calorimetrically, whereby at every desired instant the course of the decomposition of the sugar could be controlled. Sugar was the food matter of yeast for energy purposes. The vital decomposition was vastly more powerful than the fermentative. The experiments had shown that the idea expressed by Pasteur and others, that fermentation was the process of the nourishment of yeast, was correct. The automatic regulation of the consumption of energy of each cell had its own definite use; the effect of a semination of cells was proportional to the number of the same; the effect of fermentation was almost absolutely independent of the concentration of sugar; the consumption did not increase even with a very considerable amount of sugar; the consumption was even decreased by a rising concentration when the limits of plasmolytical effects were approached. The young cell which had just been created by growth had no higher consumption of energy than a cell existing without growth in a nitrogen free solution. The consumption of energy changed with every change of temperature, but the acceleration of the consumption of energy amounted, at an increase of heat of 10° only, to 1.62 times. Preserved by cold the yeast cell remained alive for a long period even without fermentation. Left to itself at a higher temperature it became decomposed by autolysis by means of an endocellular ferment known as endotryptase. Yeast possessed no metabolic assimilation in starvation; it formed no heat when placed in solutions of peptone without sugar. In this condition its life remained latent, neither could the autolytic decomposition be abolished. Sugar alone, therefore, might be regarded as the source of energy. The autolytic decomposition ceased when the living substance began to ferment. Endotryptase, the protein digesting ferment, did not even disappear during fermentation, but the fermenting vital substance was no longer attacked by it. As Ivanoff had shown, the fermentation possessed the after effect that the protein of the cells after fermentation was attacked by endotryptase with difficulty for a longer period. Endotryptase seemed to have the object of decomposing dying protein matter that it might pass out. These products of excretion were not identical with an autolytical dissolution of quiet cells. The nongrowing yeast cells showed changes which recalled the manifestations of old age. If cultivated for a long period the number of cells need not decrease, yet the effects of fermentation decreased rapidly in geometrical progression together with the loss of nitrogen; the enzymatigen effects decrease proportionally, and both together slower than the fermentation. Yeast, in order to remain alive, must become from time to time regenerated by growth. Every yeast cell received nitrogen substance from a solution of peptone which remained in the case of nonfermenting yeast as a reserve material. The fermenting yeast absorbed more than the nonfermenting and formed cellular protein. Yeast could increase up to 2.6 times the amount of nitrogen without an increase of cells, that was to say without growth. Yeast perished without growth by separation in spite of nitrogen nourishment. All agreed that living substance was composed of single small units of life; these he termed "biogenes"; they possessed two capabilities; namely, increase of their substance by separation; and dissimilation, which in the case of yeast was the fermentative power. These biogenes often lost their capability of growth; there remained simpler elements, which only possessed a rudimentary capability of separation, which he called "biontes." They composed the principal mass of the cells of fully grown organisms. Each biogene and each biont consisted of a union of many molecules of protein. The peculiar ac-

tion of yeast during the absorption of nitrogen might be explained in that the biogenes and biontes each got a certain increase in protein molecules, but that for some unknown reason the biogenes could not separate. The formation of living substance rarely took place directly, only in the case that particularly suitable protein molecules were in existence. This formation generally took place in two acts, the food material being first prepared in a suitable manner. This latter act could also take place in latent life. If genuine growth took place no increase of the consumption of energy of fermentation could be detected and in consequence no endothermal increase of energy. The living substance was no endothermal union. Calorimetrical measurements with the autolysis of yeast have proved this. The attraction for food material was enormous with the growing yeast cell. Growth and capability of fermentation had an intimate relation to one another. Maximal growth could only be obtained with a normal fermentation; this did not hold true for very high temperatures. To a maximal growth a sufficient amount of sugar to maintain the fermentation was required besides the food matter containing nitrogen. Generally a formation of alcohol hindered the maximal growth. Alcohol was more than twice as poisonous for the process of growth as for the process of fermentation, yet very minute amounts of alcohol seemed to facilitate the growth. An airing of the cultures favored the growth because thereby the greater portion of the sugar was burned and the injurious concentration of alcohol was only later met with. For all the relations of the growth to the nitrogen food the relation of the nitrogen of semination to the nitrogen of the nutritive solution was decisive. Dr. Rubner termed this the "tension of the food matter." Upon this the speed of the growth depended. In the course of every experiment the speed of growth decreased in proportion to the decrease of the food amounts. There existed a fixed limit to "the tension of food matter" which regulated the beginning of growth. This he called the "threshold of growth." The "tension of food matter" of the threshold of growth was different with different food materials. The reason of this was that different food materials possessed very different values. If yeast was offered such a quantity of food that it could carry out one cell separation completely this action constituted the threshold of growth. The stimulus of the nitrogen nourishment consisted in the rapid storage of food material in the living substance, above all in the nucleus by which a displacement of the tension of nucleoplasm of Richard Hertwig took place, and the growth began. When one considered the enormous power of growth of yeast it was not extremely surprising that it could not fully regenerate cells destroyed by nitrogen loss. The explanation of this was that the biogenes were first provided with food when nitrogen was absorbed from nutritive soil containing nitrogen. These biogenes were unable to separate because of the high threshold of growth in yeast cells. With mammals these relations were more complicated and at the same time different from those of yeast. The feeding up of cells to their normal condition proceeded in the case of mammals differently from their growth only with a relatively greater profusion of the protein diet as had been accurately shown by experiment. Even a pure diet of protein was unable again to increase the expired capability of growth, either in the case of the increasing process of growth over the typical process or to reawaken the expired capability after the cessation of growth of the fully developed body. The biogenes of the youthful organism had probably lost almost all their characteristics of growth and become biontes. Dr. Rubner believed that the reconstruction of destroyed tissues of animals must be represented by two different processes acting side by side. Firstly, by an improvement of the condition of nourishment of the biontes, which became necessary with hunger; and, secondly, by a compensation and an increase of the biontes, a filling up of the cells from organic regions externally situated. The change of the condition of nourishment of the biontes could take place, as in the case of yeast, by every suitable nitrogen food. The compensation for perished biontes without growth of cells was only possible with higher organizations. The higher organism was composed of two systems of organs, cells whose separation was excluded, and those which obtained a continuous renewal, like blood cells. Yeast belonged to the organisms which possesses the greatest amounts of energy known. Its consumption of energy was 157 times as large as that of a horse, calculated at equal units; 58 times as large as that of man, but only three times as great as that of a newborn mouse in a state of rest. The increase of the metabolism of yeast was not in the remotest way equivalent to its enormous relative area. The consumption of energy of the world of minute life depended more upon specific peculiarities of their living substance than upon other conditions. The maximal speed of growth with yeast was very considerable, about 32 times more than that of the mouse and 1,400 times as great as that of the infant. This great difference came from the fact that that maximum speed of growth had already been completed by the mammals at the beginning of extrauterine life. If one calculated the transmission of matter through the cell wall for animal cells it would be found that for equal areas less sugar was transmitted with the mammal, taking the newborn mouse for comparison, than with yeast in anaerobic life. The migration of the sugar from the fluid of the yeast cell extended only through minimal roads, the layer of sugar which contained the sugar for one complete day of fermentation had only a height of eight one-hundredths in a solution of one per cent. and only one of one four one-thousandths mm. in a solution of 20 per cent. The cells sometimes received more sugar than could be decomposed, and formed glycogen. This formation of glycogen would still take place when the living protein of the yeast had been killed or the fermentation had been otherwise prevented. By experiments with toluolized yeast he had been able to show that a reception of heat took place in the course of this deposit of glycogen. The amount was small, but could be proved calorimetrically. This bond of heat could be explained by the setting free of water molecules. In the saccharinization of glycogen heat became free; in the reversal of the process heat was naturally bound. In closing, Dr. Rubner said: "In to-day's lecture I have conducted you into the world of minute beings, but in spite of all their strange actions we have not really seen strange manifestations with them in vegetative life; only life in another milieu, but yet again customary and known in many things which are of value and importance for our understanding of the higher organisms. A forlorn little plant has taught us great things, the unity of living nature."

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held in Hartford, Conn., June 10, 11, 12 and 13, 1912.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. A. D. BLACKADER OF MONTREAL, CANADA, IN THE CHAIR.

(*Continued from page* 685.)

Chest and Shoulder Pains in Pulmonary Tuberculosis.—Dr. FRANCIS MARION POTTENGER of Monrovia, Cal., read this paper. The pains he referred to were of diagnostic importance, were frequently mistaken, and often erroneously treated. These pains varied in character from a mere uneasiness, a "feeling of being tired," which was specially noticed through the shoulders and interscapular regions, to a distinct severe localized pain. He called attention to a localized pain which might vary in its character, or might be very severe and which he believed to be a true neuritis of reflex origin. When he found a tuberculous patient who complained of aching in both scapular regions, he was inclined to believe that both lungs were involved. The aching was not confined to the scapular regions. It might be noted in the shoulders, neck, and anterior portion of the chest wall. The pains might be so severe that morphine was necessary for their relief. The interesting fact about the pains was their regional nature. They occurred on the same side as the involvement of the pulmonary parenchyma. The side of the greater pain was usually the seat of the greater amount of inflammatory change. One thing characteristic of the various pains in the neck and chest of tuberculous patients was the fact that they were not constant; they were influenced by weather conditions, being worse in damp rainy weather and more severe when the barometer was changing. He was beginning to look upon "rheumatism of the shoulder" as a condition associated with tuberculosis of the corresponding lung sufficiently often to call for a careful chest examination of all such cases. Another diagnostic hint he threw out was that any pain involving the neck and chest, whether it was the vague "feeling of being tired," experienced in the interscapular region, or a pain of marked severity, which was interrupted in character, being influenced particularly by

weather changes, should call the attention of the examiner to the necessity of a careful chest examination.

Memorabilia: Extracts from Medical Notes of the Late Dr. Henry Ingersoll Bowditch.—Dr. Vincent Y. Bowditch of Boston said that the title of his paper was the result of looking over a series of manuscripts, prepared as a résumé of his "Life Work" by his father for his Harvard Class Report Book. In this paper were given reminiscences of the teachings of the great Louis Bowditch; the development of the ova of the snail under the microscope; and his allusion to Amos Twitchell of Keene, N. H., one of the best of men and among the cleverest of physicians in the middle of the last century. One of the notes presented touched upon thoracocentesis performed with an exploring trocar and a suction pump, a subject and operation which doubtless brought Dr. Bowditch's name into prominence more than any other single work of his medical career. He was never one to dispute with others over priority of claim to any act or deed of his. At every opportunity he acknowledged his debt to Dr. Morrill Wyman of Cambridge for the first suggestion of an instrument which in a modified form he used afterwards in hundreds of cases and forced upon the medical public. Inasmuch as one or two articles had within recent years been published in which reference had been made to Dieulafoy as the inventor of thoracic aspiration, without any allusion whatever to the exhaustive work of his father upon the same subject years before, he felt that he should be pardoned for showing some filial zeal in reviewing the subject again as a matter of justice. The chief fact that remained and was after all the best to consider, apart from all personal considerations, was that thoracocentesis had brought relief to thousands of sufferers and saved lives without number. It was hard to believe that such a simple operation, one that could be applied by any practitioner of common sense and judgment, had to be forced upon the attention of the skeptical and prejudiced public of fifty or sixty years ago.

Dr. J. H. Pratt of Boston, Mass., said that he had become acquainted with much that Dr. Louis Bowditch had written in a search for memoirs. There was a freshness and a modern tone about his writings that appealed to the reader to-day. In all of Dr. Bowditch's writings one saw the results of very careful observation and a careful weighing of facts. Many of his writings could be read with both pleasure and profit to-day. Louis Bowditch was the patron saint of the Massachusetts General Hospital and Dr. Pratt had read some of his records. There were no records of physical examinations but only of histories and treatments. He found a volume which contained the report of the first autopsy done by Dr. Bowditch; it was a model of careful objective description and he wished that it might be reprinted on this account.

Colds and Pneumonia.—Dr. William Duffield Robinson of Philadelphia said that many cases of pneumonia, tuberculosis, bronchopneumonia, rheumatism, etc., had only been possible by a preceding catarrhal disease of the breathing highway named "common colds." The maintenance of vigorous health in the membranous regions involved in respiration should be a duty at all ages of life. To attain this, the essentials were cleanliness, avoidance of irritants, and of thermic shock, and when needed, the use of proper antiseptics. As a preventive and curative, an abundance of clean fresh air was nature's and man's best agent. A prolonged séance of slow deep breathing would often prevent the development of a cold if indulged in when the first well known symptoms were recognized. Colds, especially in the very young and old, led to the development of bronchopneumonia. In pneumonia, an acid blood was deemed desirable to reduce the coagulability of the blood and to inhibit the multiplication of the pneumococci. In colds, if an active alkalinity of the blood was induced early in the history, a prompt termination of the attack was secured. To secure such alkalinity, the skin must be used as a portal of introduction, as the stomach could not tolerate the required amount. Two pounds of common carbonate of sodium dissolved in a bath tub full of water at a tepid temperature was the correct strength of the solution. In this the patient should be given a fifteen-minute soak. Spraying a 1 or 2 per cent. solution of magnesium sulphate over the nasopharyngeal membrane was quite an addition to the treatment of these cases. When the respiratory passages were much irritated by a cold, much comfort and assistance toward cure resulted from the inhalation of various volatile oils. Ten or fifteen grains of a salt of quinine which actively excited leucocytosis was very effective, especially if given before there had developed structural changes in the nose, throat, and bronchial tissues. Bacterins, antitoxins, and the hypodermic use of camphorated oil were likely to steadily advance in popularity. Pneumonia was the most frequent and the most fatal of all acute infections which caused death; it caused one-eighth of all deaths, which was more than the number caused by consumption. Pneumonia occurred three times as frequently as it did fifty years ago. The extent of lung involvement was not to be relied upon as a sure index of the seriousness of any case. Active, virulent pneumococci might be present in the blood current before any evidence of involvement of any part of the lung could be recognized. The first physical change in the lungs in pneumonia was a congestion of the capillaries about the alveoli followed promptly by a clear serous exudate fully dilating the alveoli. Fibrin promptly formed in this causing consolidation. Dr. Robinson had not found any record of the finding of the pneumococcus in the first clear serous exudate; but after the integrity of the alveoli had been broken and fibrin had exuded into them, they were found abundantly. In animal experimentation on dogs and sheep it was not found easy in healthy animals to produce the disease by injecting cultures of virulent pneumococci into the bronchial tubes unless some violence occurred which probably caused trauma and hence solution of continuity. The serum of immunized animals was not effective in checking the disease as would be expected by analogy with other infections. It was thought by some that it was the exudate that caused the fever, but the exudate remaining and being absorbed after the crisis did not cause fever. No isolated toxin had been procured from the blood or culture from a pneumonic case. The most virulent pneumococci autolized much more readily than the non-virulent kind. A transition of staphylococci into pneumococci resulted from passage through the bodies of animals. With regard to the treatment of pneumonia, adrenalin given hypodermically and oxygen passed through absolute alcohol were probably the best circulatory sustaining procedures known. Strychnia properly held a most important place. Outdoor treatment was of great importance. Hot baths and copious diluents to help eliminate the products of the destroyed bacteria and leucocytes were of great value. The head should be kept low. Calomel should always be given as a first medication and constipation should be avoided. Dry cupping was comforting.

Pneumonia in Open-Air Sanatoria.—Dr. Harry Lee Barnes of Wallum Lake, R. I., read this paper and offered the following conclusions: (1) Twenty-seven sanatoria for tuberculosis, from records equivalent to observation on 13,582 patients for one year, reported 18 cases of lobar pneumonia with seven deaths, or a mortality rate of 53.99 per 100,000 population. (2) If allowance be made for a different age distribution in sanatoria from that of the general population, a normal death rate for lobar pneumonia in sanatoria should be about 28.46 per 100,000 population. (3) Thirty-eight and eight-tenths per cent. of the cases of lobar pneumonia died, the high mortality probably being due to preceding tuberculous disease. (4) If allowance was made for the high mortality rate of the cases and for the probable slight under-rating of lobar pneumonia in the census, it appeared likely that the incidence of lobar pneumonia was about the same in the sanatoria as in the general community. (5) The impression that lobar pneumonia was rare in sanatoria for tuberculosis was due to the small population under observation and to the fact that sanatorium patients were at ages which furnished but 36.6 per cent. of the lobar pneumonia cases. (6) This investigation furnished no evidence that the incidence of lobar pneumonia was influenced by the open air life in sanatoria. (7) The death rate from all forms of pneumonia in sanatoria was 117.83 instead of 32.78 per 100,000 as should be expected, the frequency being largely due to aspiration pneumonia.

Dr. Lawrason Brown of Saranac Lake, N. Y., said it was not an easy thing to make a diagnosis of pneumonia when a patient was afflicted with pulmonary tuberculosis. The mere finding of the pneumococci did not prove anything. He really questioned whether a diagnosis was ever made except at autopsy. Sometimes, following a hemoptysis, one got an involvement of an entire lobe which occasionally cleared up, but it was difficult to say positively that such a case was one of lobar pneumonia

Dr. J. H. Pratt of Boston, Mass., said that if he had understood Dr. Robinson correctly he had said that cases of so-called pneumonia coming to autopsy early showed only serous exudate; if such was the case pneumonia was not present. He had not found a single case in which autopsy was made in the initial stage where the only lesion was congestion. In a case in which death supervened at the end of twenty-four hours after the onset, there was consolidation and very little fibrin formation. There was, however, a remarkable proliferation and

desquammation of the epithelium lining the alveoli. If there were only a serous exudate in the first stage, how could a diagnosis be made?

Dr. Morris Manges of New York said that he could not see what advantage was gained by keeping the head low in pneumonia or by placing a tight binder around the patient. If the body had rest the patient would be the gainer. The use of a tight binder would not keep the vessels empty but would embarrass the movements of the diaphragm. Relying upon strychnine as a stimulant was like relying upon adrenalin; if stimulants were needed caffein and digitalis could be used. Later in the course of the disease camphor could be used.

Dr. A. D. Blackader of Montreal, Canada, said he differed from the speaker regarding the efficacy of drug medication. They all knew the effects of caffein, strychnine, and digitalis on the respiratory center and on the heart. Camphor was a temporary but prompt stimulant. Caffein was more of a heart stimulant. Action on the medulla would do good in these cases in spite of all the statements made by Cabot.

Dr. W. Duffield Robinson of Philadelphia said that they had produced pneumonia in dogs and sheep and had then killed them. During the early stages there was a closure of many of the alveolar structures and pneumococci were found. The abdominal binder kept the intestines free from gas.

Dr. Walter Alden Griffin of Sharon, Mass., gave the history of a woman with tuberculosis who was kept in bed for a week or two with a slight temperature. She was then allowed to get up. She was seized a few days later with a severe chill and there appeared distinct signs of consolidation, rusty sputum, and other symptoms of pneumonia, and the patient died after an illness of five days.

Dr. Harry Lee Barnes of Wallum Lake, R. I., said, in closing the discussion, that it was difficult in every case to make a diagnosis of pneumonia when pulmonary tuberculosis was present. He related the case of a woman who entered a sanatorium because of a temperature due to tuberculosis. Suddenly this temperature rose to 103° or 104° F., stayed there eight or nine days, and then went down with the typical crisis of pneumonia. She had a typical rusty sputum, dyspnea, and cyanosis, in fact every clinical symptom of pneumonia, and there were an enormous number of pneumococci in the sputum.

The Results of Dispensary Work in the Control of Tuberculosis.—Dr. Cleaveland Floyd of Boston said that, in order to determine as far as possible how well the dispensary met the demands made upon it, he had been for several months making a statistical study of what had been accomplished among such patients as presented themselves at the clinic of the Boston Consumptives' Hospital. All types of patients were received there who complained of pulmonary symptoms. The clinical material at their disposal had consisted largely of three groups of cases: (a) negative cases; (b) cases of non-pulmonary disease; (c) cases of pulmonary tuberculosis. The results obtained in the first 5,000 patients examined at the clinic beginning September, 1907, and continuing into the middle of the year 1909, after an average period of observation of two years and five months, had been carefully scrutinized and, with the aid of some twenty visiting nurses during a period of sixteen months, as much data as possible had been obtained. Among some 5,000 patients there were found 2,121 positive cases of phthisis, 1,130 who were suspected of having the disease, and 1,707 who were negative on the first examination. Of the remaining 42 they had insufficient data. Of this total number, 1,315 were lost to the clinic through their giving incorrect addresses or moving away. Five hundred and seventy-five were considered negative when lost to the clinic, 382 were suspected cases, and 358 had definite pulmonary tuberculosis. In other words, one-sixth of the positive cases were lost during the period of observation of two years and five months. It was only natural to expect that a larger group of negative cases should be lost sight of, as it was the custom to pay less attention to this group than to those demanding active supervision in almost any clinic. This percentage of cases that disappeared, making as it did about a fifth of their total number, would of course increase in larger cities than Boston, where population shifted more rapidly, as in New York. For those patients who moved without the city limits and consequently escaped the jurisdiction of the health board, either State supervision or a metropolitan plan of cooperation among tuberculosis clinics, it seemed to him, would be the wisest measure. By these means the floater and drifter having active tuberculosis could be more readily controlled and the work of the dispensary made productive of greater usefulness at one of its weakest points, for it was in the close following up of patients alone that they could hope to do prophylactic work as well as to increase the present value of sanatorium treatment. Among 1,707 cases who were considered negative at their first examination and whom they had been able to reexamine recently, there were still found 604 perfectly well and 528 reported themselves as well or had developed some other disease than pulmonary tuberculosis. The real test of how efficient the supervision of the clinic and its nursing force might be could be determined from the following facts: (1) How many cases under observation for a period of years who were negative to tuberculosis or suspected of having it, subsequently developed the active disease? (2) How large a proportion of the cases subsequently succumbing to the disease died in a hospital? From these facts the power of the clinic for the prevention of tuberculosis would be demonstrated and also the effectiveness of removing to places of isolation those who were sources of danger to the community. In the group of negative cases among 1,132 whom he had obtained data upon, only 24 had developed phthisis during the period of observation of two years and a half. In the group of cases classed as suspected, among 748 cases that they had been able to follow, only 62 cases developed active disease. Thus among the total of 1,880 negative and suspected cases, only 86 developed active tuberculosis. Among a total of 1,130 cases suspected of pulmonary tuberculosis, 624, or about 60 per cent., gave signs at the right apex. The other 40 per cent. were almost equally divided between questionable signs at the left apex and base. Almost without exception these signs had either cleared up or had failed to develop into active tuberculosis. Where the right apex, however, had shown questionable involvement, 62 of the number that they had been able to follow developed phthisis.

Dr. H. R. M. Landis of Philadelphia said that he had been interested in a similar work and he wished to emphasize the importance of the work the dispensaries were doing. The greatest drawback up to the present time was the attempt to cover too much territory. During the past seven years he had studied 1,100 cases and had lost sight of 320. Of the 1,100 cases, 915 were treated on the supposition that they had tuberculosis; of these 410 died, and of 184 living when the work stopped, 107 were back at work. Patients discharged from sanatoria usually had the conviction that they were cured and did not pay any attention to the doctor's orders regarding their mode of life. All cases should be strongly urged to report at intervals and should be educated in the necessity of keeping up the method of living prescribed for them.

Dr. Charles L. Minor of Asheville, N. C., said that when a patient was discharged from a sanatorium or by his physician, he should be followed up. Doctors were derelict in their duty if they did not watch these patients closely. However intelligent the patient might be he should be seen at first every two weeks, then every month, and later every three months for a period of three years. The fact that he was not absolutely well and must live the right kind of a life must be drilled into the dispensary patient.

Dr. H. H. Whitcomb of Norristown, Pa., said that the great difficulty they met with was the ignorance of their patients and especially of those who believed in taking medicine. They were in the habit of giving some placebo which caused the patient to return in order to have it refilled. If the patients were taken away from their occupation, they soon drifted back into the same condition as when first seen; proper occupation should be sought for them.

Hemic Murmurs.—Dr. Herbert F. Williams of Brooklyn, N. Y., said that during the last year or two it had seemed to him that he had met with an uncommon number of these cases and in such various stations of life that his mind was called afresh to the significance of these manifestations. Analyses in all these cases must have shown blood deterioration, which in some cases was coexistent with or preceded a tuberculous expression; in other cases there had been a persistency of these murmurs not followed by any decline in health but which made one fear that some outbreak of some kind would follow. Dr. Williams reported a case in detail which recovered after the injection of leucocytic extract, 90 c.c. being given in all. The patient was 35 years of age and his metabolism had been much disturbed. He was seized with a lobar pneumonia of great severity; on the second day the murmur, which had been confined to the subclavians, extended over the chest. Upon slight exertion, like turning in bed or coughing, there would appear an extra murmur, unusually loud and portentous. This sudden accession in the number and intensity of these hemic murmurs was interesting as well as disquieting. He had never been entirely satisfied

as to the explanation of the cause of these murmurs which had been classified as organic. A report which included a record of seven cases appeared in the November, 1908, number of the *Journal of Medical Research*, and he was informed that a further report would soon be published. In the report of these cases of pneumonia, several well-known men in New York were the observers.

Dr. Cleaveland Floyd of Boston said that he had treated 20 cases of pneumonia at the Massachusetts General Hospital with leucocytic preparations; many of these were very severe cases in alcoholics. Dr. Floyd said he did not remember the effect on the hemic murmur, but that the mortality was lowered to 12 per cent., as compared with the general mortality of 20 per cent. They had tried this method in a group of cases where there was general infection with localization in the lungs and no results whatever were obtained.

Dr. J. H. Pratt of Boston asked if the patients treated were selected cases. In the other service in the Massachusetts General Hospital where the leucocytic extract was not used at all the mortality was very low that year. The mortality from pneumonia differed from year to year.

Dr. Charles E. Quimby of New York said that he did not believe that all appreciated the changes that had occurred in the manifestations of pneumonia during the past twenty years. To-day pneumonia meant all sorts of things. At times there were vasomotor disturbances and no exudative disturbances in the lungs at all.

Dr. Herbert F. Williams of Brooklyn, N. Y., in closing the discussion, said he wished it understood that the cases were desperate ones, well-nigh hopeless, and they were not hospital cases. Giving 10 c.c. of fluid into the subcutaneous tissues was a painful operation and a hypodermic of morphine should be given, together with a local anesthetic.

Cardiac Arrhythmia, Illustrated by Lantern Slides of Polygraphic Tracings.—Dr. Thomas A. Claytor of Washington, D. C., said that auricular fibrillation (the wholly irregular pulse) was characterized by an entire loss of the sinus or fundamental rhythm; the beats were irregular both as to time and as to volume. In the venous tracing the auricular wave was missing; in other words, there was no auricular contraction, the venous pulse being of the ventricular or positive type. There was a general fibrillary contraction of the auricular muscle, but no contraction of the muscle in mass. The electrocardiograms showed an absence of the P wave (auricular contraction) and by a series of fine undulations that there were a number of impulses at the rate of four to nine hundred a minute trying to get through to the ventricles. Of course, the ventricles were unable to respond to anything like this number and hence responded only as they might; this resulted in absolute irregularity. With regard to the pathology of the auricular fibrillations, the heart muscle as a whole showed a more or less marked grade of inflammatory changes, resulting in fibrosis. The morbid changes were said to be particularly marked in the auricular tissue, especially at the sinoauricular junction; the same changes had been noted in the auriculo-ventricular bundle and in scattered areas of the ventricular musculature. Though these very decided changes had been noted in cases of auricular fibrillation just the same conditions had been found where during life the rhythm had been normal. It was in this form of irregularity that digitalis had been found of the greatest value. It apparently acted by cutting down the number of contractions which got through to the ventricle. The prognosis was not good. The pulsus alternans was not properly a disorder in the cardiac rhythm and this form of irregular pulse was seen clinically under two sets of circumstances, namely: (1) when the apparently healthy muscle was overtaxed, especially when the rate was unusually rapid, as in tachycardia; (2) when the musculature was profoundly affected, usually by senile changes. In conclusion, the speaker said that physiologists and anatomists had materially advanced their knowledge of the heart mechanism and that they had been ably supported by a few clinicians; but it was now necessary that more of the latter enter the field and by careful observation and records of clinical cases try to clear up the many important points yet unsolved. Even a very superficial study of the cardiac arrhythmias would convince one that they were intensely interesting and very important for prognosis and therapeutics.

Dr. J. H. Pratt of Boston said that he thought it of the greatest importance to be able to distinguish between extrasystole and auricular fibrillation, but he believed this could be done in the majority of cases by palpation of the pulse alone. One should measure the length of the beats; if they were irregular, one might be sure that he was dealing with auricular fibrillation.

Dr. Thomas A. Claytor of Washington, D. C., said he believed that pulse tracings should be taught in medical schools. This was difficult, however, without some previous experience with the study of the pulse.

The Auscultation of the Whispered Voice.—Dr. Morris Manges of New York said that the whispered bronchial voice was a sign the value of which was often neglected in the detection of early infiltration of the lung. It was also useful in pneumonia in determining whether the signs of consolidation which were heard on the sound side were transmitted or not, as it was the only sign of consolidation which could not be transmitted to the sound side. He urged that while the range of usefulness of the auscultation of the whispered voice was not as great as some of its advocates would claim, yet it could often afford so much information that its routine use in physical examination should not be neglected as much as had been the case.

Dr. Judson Daland of Philadelphia said that the main point was the usefulness of the auscultation of the whispered voice in small consolidations and where one did not wish to have the patient disturbed more than was necessary, particularly in cases of hemorrhage. The auscultation of the whispered voice was especially useful when they were dealing with disseminated consolidations. These findings should be checked up by the skiagraph.

Dr. J. M. Anders of Philadelphia said a great deal might be learned by careful inspection. He had never known of one side being affected where the opposite side did not show a greater motility.

A Study of Primary Malignant Disease of the Lung.—Dr. Roland G. Curtin of Philadelphia said that the rarity of primary cancer of the lung was shown by the statistics of Dr. John A. McGlinn of Philadelphia, who recently collected the data from the post-mortem rooms at the Philadelphia General Hospital. In 8,515 consecutive post mortems he found 457 bodies with cancer, and of these only four were primary cancer of the lung. The statistics of Dr. Curtin's own cases showed that he had met with seven cases of primary carcinoma and sarcoma of the lung; the males numbered four, the females two, and there was one male with sarcoma of the lung. There were four cases with and three without effusion. The right side was involved in six cases, the left in one. Four cases were tapped and three were not. The tapping did not relieve two and two were only slightly relieved. There was marked dyspnea in six of the seven cases. The average age of the patients was 52. The average age of Dr. McGlinn's cases was 42 years; Dr. Musser's cases averaged 55 years. The most common complication was metastases in the surrounding tissues; most commonly the pleura was affected. The first symptom was often a gradual loss of flesh, more likely to be present in carcinoma than in sarcoma. Pain might be slight at first and was generally on the side affected. There was sometimes a blood spitting that was so characteristic that a diagnosis might be made from it alone. There was a dark purple globule of blood encased in a transparent glazed membrane about the size of the end of the little finger. It was sometimes lobulated or it might be rounded in form. The color was like grapes or dark currant jelly. The surrounding fluid was clear and unmixed with blood. The physical signs were those of a solid tumor or those of pleurisy.

Dr. J. N. Hall of Denver, Colo., said he had noticed when attempting to make a diagnosis by means of puncture that nodules developed along the site of puncture. He asked if this was common in the experience of others.

Dr. J. H. Elliott of Toronto, Canada, said that a striking feature of primary cancer of the lungs was that the expectoration was not purulent and hemoptysis occurred later than in cases of pulmonary tuberculosis. At no time would there be currant jelly expectoration, but a mucoid expectoration. Many cases that were regarded as primary malignant disease were not such at all. Dr. Elliott cited the case of a man with a primary growth of the left bronchus; he gradually died with marked secondaries in the liver and other organs. He had had hemoptysis for many months before he sought assistance. The hemoptysis was the leading feature in this instance.

Dr. Morris Manges of New York said he had seen two cases of new growth of the lung diagnosed by hardening the sputum and then cutting it as one would cut sections. The presence of small thoracic glands in the fourth and fifth spaces was not infrequently met with. The fluid removed by aspiration in these cases was usually large in amount and bloody. Cytology could not be used because of the bloody mucus. The failure to give relief by aspiration was very often due to an enlarged bronchial gland which, by its pressure, caused dyspnea.

Dr. Vincent Y. Bowditch of Boston reported a case that he had seen where there was dullness at the right

apex with fever and bloody sputum, all misleading. There was deep dyspnea. A diagnosis of incipient tuberculosis was made. One day he was called and found the patient in a fearful condition, gasping for breath. The patient was aspirated and experienced some relief. He ate a hearty supper and fell back dead. This was a case of malignant disease of the lung.

Dr. J. H. Pratt of Boston said he wished to endorse what Dr. Bowditch had said. He had seen the patient referred to before the others saw him, and even with that experience before him he would now have difficulty in making a diagnosis in such a case. The patient showed classical signs of a beginning tuberculosis. Dr. Walter Alden Griffin of Sharon, Mass., said that the patient showed signs of a beginning tuberculosis. The autopsy did not discover any definite point of beginning malignant disease, but they concluded that the disease started in the mediastinum and called it lymphadenoma. Dr. Griffin said he had seen one other case of malignant disease of the lung which presumably started in the mediastinum and was dermoid cystic in character. It did not involve the lung but pushed the lung aside.

Dr. Edward R. Baldwin of Saranac Lake, N. Y., reported a case of sarcoma of the pleura which had been diagnosed as tuberculosis. The patient had all the cardinal symptoms of tuberculosis. The autopsy made some months later showed sarcoma of the pleura which extended through into the mediastinum and finally involved the abdomen and peritoneum.

Dr. A. Jacobi of New York said that his experience with these cases was not as large as that of some of the others present, but he had seen cases of mediastinal adenomata; in one case the growth was very large and the glands were enlarged at about the fourth or fifth rib. It was his impression that a large number of these cases of carcinoma of the lungs were secondary, and that the primary cases were very rare. So far as the treatment of these cases was concerned, Dr. Jacobi believed that modern surgery of the chest would be of some service provided the diagnosis was made early enough. The book of Isaac Adler would be found of value to those interested in this work.

Dr. Roland G. Curtin of Philadelphia said, in answer to Dr. Hall's question, that he had never seen nodules develop after puncture of the chest. The cases reported seemed to him more like sarcoma than carcinoma. If pus was present it was late in the disease. He had participated in four post-mortems and in all of them the secretions, blood and serum, were encapsulated. He had never seen a case where the pleural cavity was occupied by one mass of fluid.

Concerning Chronic Septic Endocarditis.—Dr. Glentworth R. Butler of Brooklyn, N. Y., said that for a number of years certain cases of endocarditis had attracted attention because of their latency and long duration. About 250 such cases had been studied by Osler, Libman, Billings, and others, so that now they were in a position to define it as a distinct entity among the endocarditides. In the great majority of instances there was a bacteriemia, and by far the most common organism found was a streptococcus; this grew poorly and produced a green pigment in the process. The pathological anatomy was that of a vegetative rather than an ulcerative endocarditis. The long duration of this form of endocarditis was one of the striking features; it was the chronicity of the disease which first attracted to it the attention of clinicians. It ran a course of from four to twelve months and even longer. From a clinical point of view, its latency was remarkable. Commonly there was not a leucocytosis; after the disease had progressed for some time there was a progressive anemia. This form of endocarditis was almost invariably engrafted upon an old mitral or aortic valvular lesion. Among the other signs, enlargement of the spleen could usually be demonstrated. Gastrointestinal disturbances occurred. Pains in the joints, bones, muscles or various nerves were very common. Petechial spots developed in the majority of the cases. The appearance of ephemeral cutaneous nodes was said by Osler to be pathognomonic of this form of endocarditis. The diagnosis during the early stages was difficult. The prognosis was unfavorable.

Dr. Charles L. Minor of Asheville, N. C., said Dr. Libman of New York City had stated that certain of these cases were due to the influenza bacillus and not to the streptococcus. Dr. Rosenow of Chicago had stated that many of these cases were due to the pneumococcus. This appeared to show the polymorphism of the germ. The lesion in the heart was followed by definite lesions elsewhere. For instance, in a lesion of the aortic valve, the lesion crossed to the mitral valve, then to the chordæ tendineæ, then to the columnæ carneæ, and possibly ulceration occurred.

Dr. Herbert Maxon King of Liberty, N. Y., said that during the past year and a half he had seen two cases at the Loomis Sanitarium and in both instances the diagnosis made was tuberculosis. This showed the frequency with which the condition was confused with tuberculosis. In both cases there was a history of rheumatism and endocarditis in childhood. In the first case there was a polymorphonuclear leucocytosis which was rather suspicious. The blood culture resulted in the recovery of the streptococcus. The patient was with them for nine or ten months and did not develop petechial spots until two or three months before his death. The second case came to the sanatorium with an enormously enlarged spleen which filled the entire left side of the abdomen and was very suggestive of Banti's disease. There were large areas of petechial spots over definitely separated parts of the body. There was every appearance of septic endocarditis. He was surprised to learn that the condition was so frequently mistaken for tuberculosis. It seemed to him that tuberculosis could be excluded by a very careful examination and observation.

Dr. Morris Manges of New York said that these cases were not rare and that the picture was so characteristic that after seeing a number of cases one could not mistake them. One should carefully inspect the conjunctiva and the mucous membranes. The petechiæ were often found in the mucous membrane of the lower eyelid. They were also found in the folds of the axilla. Painful nodes alongside the big toe or on the hands (the favorite place being about the finger nails) were absolutely characteristic of the disease. These nodes lasted four or five days and then disappeared. Blood cultures taken a dozen or more times might give negative results. Dr. Butler had failed to mention the cases due to the gonococcus; these were rare but they did occur. In these cases there was a polymorphonuclear leucocytosis. Dr. Manges then referred to characteristic kidney lesions, which occurred only in ulcerative endocarditis and which had been described recently before the New York Pathological Society. In following these cases up one found that some of them would have a spontaneous cure. This made it possible for them to revise their prognosis. Thus far the vaccines, both stock and autogenous, had proved useless. Remissions sometimes occurred which lasted for months, but after a time the disease would resume its course. Hemorrhage was a curious feature of this disease, giving a clue to those who were not familiar with its manifestations.

Dr. J. H. Elliott of Toronto, Canada, said he had seen an interesting case in a woman, 25 years of age, who had a mitral stenosis. She played tennis and developed an influenzal cold. The fever persisted and a cough and changes in the lungs suggested tuberculosis. Occasional râles changed from day to day with the position of the patient. Finally a diagnosis of septic endocarditis was made. Signs of mitral insufficiency developed and then embolism of the tibial artery, which was followed by dry gangrene of the extremities. This was followed by a thrombosis of the femoral artery which at autopsy was found to extend one-half an inch through the iliac into the aorta.

Dr. A. Jacobi of New York said that Dr. Osler was the first to call attention to the fact that there was often an entire absence of symptoms in these cases. Where symptoms were absent the fact was explained by the deposits being located away from the edge of the valve so that they did not change the direction of the blood current.

Dr. Glentworth R. Butler of Brooklyn, N. Y., in closing the discussion, said that in the early stages there was leucopenia rather than leucocytosis. In the second stage a leucocytosis did make its appearance; in his series of cases it was not common in the ulcerative type.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Louisiana State Board of Medical Examiners.

May 30, 31, and June 1, 1912.

(Concluded from page 689.)

OBSTETRICS.

1. Describe the fetal circulation.

2. What is the conjugate and transverse diameters of the inlet and outlet of the pelvis? Give the anatomical points of the measurements.

3. Enumerate (*a*) the causes of delayed labor, (*b*) the dangers, (*c*) management.

4. State the causes of post-partum hemorrhage and the treatment.
5. Describe the third stage of labor, the dangers which attend it, and the methods of conducting it.
6. Mention two conditions liable to cause prolapse of the cord and the treatment for one condition mentioned.
7. What can be determined by external palpation of the pregnant woman at term?
8. Give (*a*) causes, (*b*) diagnosis, (*c*) mechanism, and (*d*) management of a face presentation.
9. Name the diameters of the fetal head.
10. Describe an embryo at the second month.

GYNECOLOGY.

1. Give a description of the physiology of menstruation.
2. What are the causes of hemorrhage from the non-pregnant uterus? Give the treatment for any two of the number which you mention.
3. What is urethral caruncle and its treatment?
4. Give the etiology and treatment of acute general cystitis.
5. Why is gonorrhea in women a grave disease?
6. Define salpingitis and state its causes and pathology.
7. What are the most common benign growths found in the cavity of the uterus?
8. Give the symptoms of ovarian cyst. What is the treatment?
9. Give the physical signs of cancer of the uterus at an early stage.
10. Describe the technique for supravaginal hysterectomy.

SURGERY.

1. How would you treat a compound fracture, say, of the tibia?
2. What is talipes equinovarus? Give treatment.
3. Give diagnosis and treatment of epithelioma of the lower lip.
4. Give symptoms and treatment of ulcer of the pylorus.
5. A woman comes to you with a lump in her breast, what steps would you take in order to make a diagnosis and how would you treat it?
6. Give signs, symptoms, and treatment of aneurysm of the popliteal artery.
7. What is a wen? How would you treat it?
8. What is varicocele? How would you treat it?
9. Give symptoms and treatment of enlarged prostate.
10. Describe briefly the Bassini operation for inguinal hernia.

HYGIENE.

1. Name and describe briefly the different methods of domestic water purification.
2. What are the most important foreign ingredients, organic and inorganic, in water.
3. What are the major sanitary details in the production and marketing of pure milk?
4. What is Pasteurization of milk and what are its advantages and disadvantages?
5. What are the relative merits of formaldehyde and sulphur dioxide as disinfectants, and in what form and in what manner are they applied?
6. What are the sources of the impurities in air and what relation do these impurities bear to health?
7. What sanitary measures should be instituted in the care of a typhoid patient?
8. What is understood by (*a*) natural immunity; (*b*) acquired immunity; (*c*) give examples; (*d*) what are the causes of immunity?
9. How is tuberculosis detected in the cow?
10. What diseases of the (*a*) skin, (*b*) spine, (*c*) respiratory tract, (*d*) digestive system, (*e*) throat are especially prevalent in school children, and how would you detect eyestrain, adenoids, trachoma, and infectious catarrhal conjunctivitis?

ANSWERS.

OBSTETRICS.

1. *Fetal circulation.* "The blood returning from the placenta, after having received oxygen and being freed from carbonic acid, is carried by the umbilical vein to the under surface of the liver; here a portion of it passes through the ductus venosus into the ascending vena cava, while the remainder flows through the liver and passes into the vena cava by the hepatic veins. When the blood is emptied into the right auricle, it is directed by the Eustachian valve through the foramen ovale, into the left auricle, thence into the left ventricle, and so into the aorta and to all parts of the system. The venous blood returning from the head and upper extremities is emptied, by the superior vena cava, into the right auricle, from which it passes into the right ventricle, and thence into the pulmonary artery. Owing to the condition of the lung only a small portion flows through the pulmonary capillaries, the greater part passing through the ductus arteriosus, which opens into the aorta at a point below the origin of the carotid and subclavian arteries. The mixed blood now passes down the aorta to supply the lower extremities, but a portion of it is directed, by the hypogastric arteries, to the placenta, to be again oxygenated." (Brubaker.)

2. The *conjugate diameter* of the *inlet* of the pelvis is a line drawn down the middle of the sacral promontory to the top of the symphysis pubis. It is about four inches in length. The *transverse diameter* of the *inlet* of the pelvis is a line drawn right across the pelvis from one lateral margin of the brim to the other. It is about five inches in length. The *conjugate diameter* of the *outlet* of the pelvis is a line drawn from the tip of the coccyx to the lower surface of the symphysis pubis. It is about five inches in length. The *transverse diameter* of the *outlet* of the pelvis is a line extending across the pelvis from one tuberosity of the ischium to the other. It is about four inches in length.

3. DELAYED LABOR. *Causes:* Obstruction, uterine inertia, uterine exhaustion. *Dangers:* Asphyxiation of fetus, post-partum hemorrhage, sepsis, pressure-necrosis and fistulæ, exhaustion or death of the mother. *Management:* The case should be treated early; causes should be removed when possible; a warm vaginal douche, and the administration of morphine, chloral, or quinine have been recommended; delivery by forceps may be necessary.

4. POST-PARTUM HEMORRHAGE. *Causes:* Anything interfering with the firm contraction of the uterus after the expulsion of the child; retained placenta, or membrane, or clots; weakness of the uterine muscle; rapid labor; delayed labor; poorly developed uterine muscle; inflammation or disease of uterus.

Treatment: Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

5. In the *third stage of labor* the physician should seize the fundus of the uterus through the abdominal wall and knead and rub it until it contracts vigorously; then he should press it down in the direction of the axis of the pelvic inlet. This should last for about a quarter of an hour after the child is born. The placenta, after it is expressed, should be carefully taken by the physician so as to be sure that it is *all* expelled; at the same time care must be taken that no particle of membrane remains behind. Fluid extract of ergot may be administered. The *dangers* are: hemorrhage; retained placenta or clots or pieces of the membranes; and sepsis.

6. PROLAPSE OF THE CORD. *Two causes:* Excessive length of the cord, and hydramnios. *Treatment* consists in: (1) Not rupturing the membranes prematurely, unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually, or with some form of repositor; (4) speedy delivery by forceps or podalic version.

7. Whether the fetus is alive or dead; whether the pregnancy is single or multiple; the presentation and position of the fetus.

8. FACE PRESENTATIONS. *Causes:* Anything which interferes with the flexion of the chin, such as goiter or other tumors, hydrothorax, a very large fetal head, uterine tumors, several coils of the cord around the neck.

Diagnosis: "The unusually prominent bulk of the cranial vault is felt in one hypogastric region; a deep groove between the occiput and the child's back may often be made out. The fetal heart-sounds are loudest over the anterior surface of the fetus, or on that side of the maternal abdomen upon which the fetal extremities are felt. The diagnosis, however, must usually rest on a digital examination, which shows before the onset of labor a high situation of the presenting part; a flattening of the anterior vaginal vault; a sharp contrast between the smooth outline of the fetal forehead and the irregular contour of the face. As

soon as the os is dilated, the characteristic features of the face may be felt."—*Mechanism:* The successive steps are: Extension—The head presents at the superior strait imperfectly extended, so that every case of face presentation may be said to begin as a brow presentation. There is also at first imperfect engagement of the presenting part, on account of the large diameters presented at the superior strait. Under the influence of the expulsive action of the uterus and the resistance of the pelvic walls, the brow, caught upon the pelvic brim, is held stationary, while the chin descends lower and lower by an extreme extension of the head. Molding, or an accommodation of the shape of the presenting part to the shape of pelvis, occurs to a moderate degree or not at all, because the face is a loose fit in the normal pelvis. The molding is confined to the back of the skull. Lateral inclination is a constant feature, so that one cheek is a little deeper in the pelvic canal than the other one. Descent of the presenting part follows the dilatation of the cervical canal, the descent of the chin being accomplished almost solely by the extension of the head, and not by a descent of the head as a whole. Anterior rotation of the chin occurs as soon as it encounters the resistance of the pelvic floor. Anterior rotation is followed by the engagement of the chin under the symphysis pubis. Then follows the delivery of the head by flexion and propulsion, the mouth, nose, eyes, and forehead sweeping over the perineum and appearing successively at the posterior commissure. Restitution and external rotation follow the escape of the head from the same causes that impose those movements upon the head in a vertex presentation. The delivery of the body takes place as in a vertex presentation."—(Hirst's *Obstetrics.*)

Management: If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backwards. Spontaneous version may occur, and the presentation become a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful, podalic version should be tried. If, after all these manipulations, the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

9. The fetal head has the following diameters: Occipito-frontal, occipito-mental, bitemporal, biparietal, suboccipito-bregmatic, trachelo-bregmatic, and mento-bregmatic. Of these, the occipito-frontal is 4½ inches; the occipito-mental is 5½ inches, and all the others are approximately 3½ inches.

10. *Second Month:* "The embryo is still markedly bent on itself, and the visceral clefts and arches are the most prominent characteristics of its cephalic region, while the extremities are in a very rudimentary condition. In the latter part of the month, owing to the development of the brain, the head becomes considerably larger, and assumes a certain resemblance to that of a human being. At the same time the nose, mouth, and ears become less prominent and the extremities more developed, so that it can be seen that they are made up of three portions. The external genitalia also make their appearance in the latter part of this month, and at its end the fetus has attained a length of 1 inch."—(Williams.)

GYNECOLOGY.

1. *Menstruation* is a periodic discharge of blood from the mucous membrane of the uterus, due to a fatty degeneration of the small blood-vessels. Under the pressure of an increased amount of blood in the reproductive organs, attending the process of ovulation, the blood-vessels rupture, and a hemorrhage takes place into the uterine cavity; thence it passes into the vagina. Menstruation lasts from five to six days, and the average amount of blood is about five ounces. It begins at puberty and occurs periodically at about 28 days interval, until the menopause; it is absent during pregnancy and early lactation.

2. *Hemarrhages occurring in the non-pregnant woman:*

A. In virgins before the age of thirty: Caused by (1) uterine congestion, the result of cold or exposure; (2) endometritis; (3) polypi and fibroid tumors.

B. In married women before the age of thirty: Caused by (1) subinvolution; (2) laceration of the cervix; (3) endometritis; (4) retrodisplacements of the uterus; (5) polypi and fibroid tumors.

C. In women after the age of thirty: Caused by (1) carcinoma of the cervix; (2) carcinoma of the body of the uterus; (3) sarcoma of the uterus.

Lacerations of the cervix should be repaired; and for carcinoma of the cervix, hysterectomy is indicated.

3. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

4. CYSTITIS. *Causes:* Retention of urine, tumors, foreign bodies, calculus, ammoniacal urine, gonorrhea, tuberculosis of genitourinary tract, pus in the urine.

Treatment: Rest in bed; the imbibition of plenty of milk and water, and the avoidance of all highly seasoned food; laxatives; diuretics; sitz-bath; irrigation of the bladder with an antiseptic solution; hot fomentation and vaginal douches are often helpful; sometimes intravesical medication is necessary.

5. Because it may be followed by: Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condyloma of vulva, abscess of Bartholin's glands.

6. *Salpingitis* is inflammation of the Fallopian tube. *Causes:* Gonorrhea, septic infection, subinvolution, fibroids, uterine displacements, lacerated cervix, taking cold at menstrual periods, and certain diseases such as the eruptive fevers and syphilis or tuberculosis. *Pathology:* "The inflammation usually extends all along the mucous membrane of the tube to the fimbriæ and ovary. The abdominal opening is closed by adhesions, thus preventing escape of the contents of the tube into the abdominal cavity. Resolution is rare. At first there is a hyperemia of the mucous membrane more or less intense; later, swelling and softening of the tube, the tissues becoming friable; the fimbriæ share in the swelling. The mucous membrane is covered with a glutinous pus. Usually the abdominal opening now closes from adhesion. The uterine opening may remain patulous to permit the escape of the tubal contents. In some cases, however, the swelling of the mucous membrane is sufficient to close this ostium, and thus cause a retention cyst. The uterine end of the cyst may later open from pressure and the contents be discharged through the uterus at intervals. When the cyst contains clear mucus, it is known as *hydrosalpynx;* when blood is retained, *hematosalpynx;* when purulent, *pyasalpynx.* The dilatation usually occurs in the outer two-thirds of the tube."—(From Wells' *Gynecology.*)

7. Fibroids and polypi.

8. An ovarian cyst is generally accompanied by menorrhagia or metrorrhagia, sterility, bearing down pain in the pelvis, which may radiate to the back or thighs, hemorrhoids or constipation, frequent micturition, and various other pressure symptoms of the digestive or respiratory apparatus if the cyst becomes sufficiently large. Later on there may be the *facies ovariana,* general impairment of health, and ascites. There are no pathognomonic symptoms. The diagnosis is made by bimanual palpation and (sometimes) exploratory incision. The condition is to be particularly differentiated from pregnancy and ascites.

The *treatment* is ovariotomy.

9. Hemorrhage, leucorrhea, foul-smelling discharge, and pain.

10. *Abdominal hysterectomy.* "The patient must be carefully prepared as for any other abdominal operation, but in addition the pubes and vulva must be shaved and thoroughly purified; the vagina should be douched for some days previously, and an antiseptic dressing worn, and if need be the uterine canal should be curetted and disinfected with some powerful antiseptic.

"After anesthesia has been induced the Trendelenburg position is adopted, and an incision of suitable length made in the median line. The parts are then carefully explored, and if no adhesions exist an abdominal cloth is packed in over the intestines in order to protect and keep them from exposure and injury. If adhesions to omentum or gut are present they must be carefully divided; it is, of course, most desirable that a complete peritoneal covering should be secured for any adherent organs; omental grafts may be sometimes useful in this direction. The broad ligaments are then examined, and a decision made as to whether or not the ovaries and tubes are to be saved.

"A pedicle needle carrying a sufficient length of well-boiled silk is carried through the round ligament so as to secure the ovarian artery and veins, and tied as far away from the uterus as possible. A broad ligament clamp may then be placed in position close to the uterus, so as to prevent venous regurgitation, and the broad ligament is divided half-way down. It is often possible and desirable to pick up the divided end of the ovarian artery on the face of this section and secure it separately, while the little artery which accompanies the round ligament should also be carefully secured. The ovarian artery on the other side is next dealt with in a similar fashion. A transverse

cut is now made across the front of the uterus, involving merely the serous membrane and connecting the two ends of the incisions in the broad ligaments; the peritoneum below this transverse cut is detached, together with the bladder, from the cervix, and the intraligamentary space is thereby opened up on either side. In this will be found the uterine vessels, and it may be possible to see and isolate the uterine artery before securing it by ligature. Care must be taken in this part of the operation to keep close to the uterus, as the ureter comes forward from behind under the uterine artery to reach the bladder, lying about the level of the os internum. The uterine vessels are in this way carefully secured and divided.

"The uterus is now merely held by the connection between the vagina and cervix and the peritoneal reflection in Douglas's pouch. If a supra-vaginal operation will suffice, the surgeon cuts across the neck of the uterus in such a way as to fashion two flaps, and finally the peritoneum behind is divided. A few small vessels will probably need to be secured on the face of the uterine stump. This having been effected, the uterine flaps are stitched carefully together so as to bury the open cervical canal; the uterine stump is then covered in by uniting the divided portions of peritoneum. This line of sutures is carried up on either side so as to secure the two layers of the broad ligament; the final result is that the pelvic floor is covered in by a continuous layer of peritoneum, showing a sutured incision which runs transversely from one side to the other. The usual peritoneal toilette follows, and the abdomen is generally closed entirely, no drainage being required."—(Rose and Carless' *Surgery*.)

SURGERY.

1. The most important thing is to render the wound aseptic by enlarging it and washing its depths and surroundings thoroughly with 1 in 20 carbolic or 1 in 500 biniodide. An anesthetic is necessary. Loose fragments should be removed, hemorrhage dealt with, and the bones fixed by wires or screws. The wound should be drained by a tube at the most dependent spot, and the rest of the wound closed. The limb should then be fixed on a splint, the foot at right angles to the leg and the heel kept off the splint by pads. The inner border of the patella, the inner malleolus and the inner border of the ball of the big toe should be in a straight line.

2. *Talipes equino-varus* is a deformity in which the heel is drawn up, and the anterior part of the foot is inverted and drawn inwards.

Treatment: "It may be treated in the early stages by fixing the foot in good position by a series of plaster-of-Paris casings, or by using a malleable metal splint. Tenotomy of tendons which hinder reduction in some cases is necessary, with the subsequent application of plasters. If the ligaments on the inner side of the ankle hinder reduction, they should be divided. In the neglected cases, where the patient has been walking on the outer side of the foot, tarsectomy is necessary. A wedge of bone, with its base outwards, is removed by a chisel or saw, irrespective of the joints, from the tarsus in front of the peroneal groove on the cuboid. The foot can then be brought into good position, and maintained so by plaster-of-Paris."—(*Aids to Surgery*.)

3. *Epithelioma of the lower lip* generally begins as a fissure, which becomes indurated, then ulcerates and extends; sometimes it is nodulated or looks like a wart. The submaxillary and submental glands become enlarged and hard. Diagnosis may be made certain by microscopical examination of a small piece removed for the purpose. Treatment consists in thorough removal of a wedge-shaped piece with at least half an inch margin. The glands should also be removed from both sides.

4. The *symptoms of ulcer of the pylorus* are: Localized pain, tenderness, vomiting, hematemesis, hyperacidity, dyspepsia, loss of strength, anemia; pain is severe, and generally comes on about an hour after eating. Examination of the stomach contents usually shows an increase in the hydrochloric acid.

Treatment demands rest in bed, liquid diet or rectal feeding; opium may be necessary; iron and arsenic may help the anemia; perforation demands an abdominal section and rectal feeding. The ulcer may be excised; sometimes a gastro-jejunostomy is done.

5. The breast should be thoroughly and carefully examined. Diagnosis is generally easy in advanced cases; "but in the early stages, when radical treatment is so essential, a cancerous tumor may be confused with inflammatory and other benign swellings. In *chronic inflammatory thickening* the skin may be pitted, and the tumor fixed in the breast, and ill-defined; but the whole gland is often uniformly enlarged, scars of old abscesses may be visible, and the glands are swollen at an earlier stage, and to greater size than in cancerous conditions. *Adenomata* are generally clearly limited and freely movable; there is no dimpling of the skin, and the lymphatic glands are not enlarged. *Tense cysts*, when fluctuation cannot be elicited, are similar in most of their symptoms to adenomata; and differ from 'malignant cysts' by the absence of adhesions or extension of the disease to lymphatics. *Sarcomata* are more rapid in growth and soon involve the skin, and do not affect the glands in the early stages. *Duct cancers* are apt to be multiple, are more circumscribed, and are specially distinguished from scirrhus by the bloody discharge from the nipple; they differ also from simple papilliferous cysts of the ducts by the tumor invading the breast. *Epithelioma* of the areola or nipple differs from eczema in its intractability to soothing treatment; and from scirrhus in its superficial and more localized situation, at all events in the early stages. In cases of *doubtful* diagnosis it is advisable to prepare for a radical extirpation of the disease; but first to incise the tumor and *remove a piece* from the growing edge for immediate examination."—(Buchanan's *Surgery*.)

Benign tumors should be removed; malignant, if operable, require entire removal of the breast and neighboring lymphatics.

6. *Popliteal aneurysm* is generally due to disease of the artery, although repeated slight strains, which are so liable to occur at the knee, may play an important part in determining its formation. The aneurysm is usually sacculated, and may spring from the front or from the back of the vessel. It may exert pressure on the bones and ligaments of the joint, and it has been known to open into the articulation. The pain, stiffness, and effusion into the joint which accompany these changes often lead to an erroneous diagnosis of joint disease. The sac may press upon the popliteal artery or vein, causing congestion and œdema of the leg, and leading to gangrene. Pressure on the popliteal nerves gives rise to severe pain, muscular cramp, and weakness of the leg. The differential diagnosis is to be made from abscess, bursal cyst, enlarged glands and sarcoma. The choice of operation lies between ligation of the femoral artery in Hunter's canal, enucleation of the sac, and Matas' operation of aneurysmo-arteriorraphy."—(Thomson and Miles' *Surgery*.)

7. A *wen* is a sebacious cyst in the scalp. It should be dissected out with the capsule; if possible, the latter should not be broken.

8. A *varicocele* is a varicose condition of the pampiniform plexus. The patient should wear a suspensory bandage, or a portion of the dilated veins may be excised.

9. ENLARGED PROSTATE. *Symptoms:* Slowness in starting urination; difficult micturition; frequency of micturition, particularly at night; the presence of residual urine; dull, aching pain in the perineum and above the pubes; enlargement of the lateral lobes of the prostate; there may be cystitis and retention of urine. The *cause:* It is a senile change, and may be due to increase of the glandular substance or of the interstitial fibrous or muscular tissue. *Palliative treatment* consists in: Mild and unirritating diet, avoidance of alcohol, taking plenty of milk or water, or other diluent. Alkalies and sedatives should be taken, also urotropin or other antiseptic so as to prevent cystitis. Regular catheterization, at least once a day, preferably in the evening, and with due aseptic precautions. *Operative treatment* consists in prostatectomy.

10. *Bassini's operation:* "An incision 2½ inches long is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three or four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or, if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterwards for six months."—(From *Aids to Surgery*.)

HYGIENE.

1. *Domestic water purification* can be accomplished by filtration and boiling. But the filter must be kept clean; and after boiling the water should be put in a perfectly clean container and covered.

2. FOREIGN INGREDIENTS IN WATER. *Organic:* Particles of animal and vegetable matter; bacteria and other living organisms, animal and vegetable; gases; ammonia, nitrites, and nitrates. *Inorganic:* Particles of mineral origin; gases; salts (chlorides, sulphates, carbonates, silicates, nitrates, nitrites, phosphates), lead, iron, soda, magnesia, lime.

3. The milk may come from a diseased cow; it may become contaminated by the milker, the container, the surroundings, the water used to wash the cans or to adulterate the milk; or it may become contaminated at the dealer's or purchaser's house by being left uncovered, exposed to flies, etc., or by not being kept in a cool place. The only way to prevent the transmission of disease by milk is to insist on a thorough inspection of all dairies and sources of milk supply, and to educate the public in the care of milk between the time of its purchase and its consumption. The inspection should include: the color, reaction, specific gravity, sediment, taste, odor, acidity, total quantity of solids and of water; the percentage of cream, fats, lactose, casein, and ash; the presence or absence of preservatives, coloring matter, added solids, dilution, pathogenic microorganism, dirt, or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transporting the milk.

4. *Pasteurization of milk* consists in heating the milk for twenty minutes at a temperature of 140° F.

"Advantages of pasteurization milk: (1) That most, if not all, of the common bacteria and their toxins are killed. (2) That the ordinary ferments and germicidal properties of the milk are not destroyed. (3) That the process may be accomplished on a large scale, and furnish a commercially safe milk. (4) That the taste, appearance, odor, and cream separation quality of the milk are not altered. (5) That pasteurized milk, if kept cold, furnishes a clean, healthy milk, safe for infant food and other uses.

"Disadvantages of the pasteurization of milk: The following are some of the objections which are urged by the opponents of pasteurization upon a large and commercial basis: (1) That the spore-bearing bacteria and bacterial toxins are not destroyed, and the milk is therefore not wholly safe. (2) That pasteurization stops lactic-acid fermentation, and thus destroys the only 'nature's danger signal,' and the first symptom by which aged milk is known. (3) That unless pasteurized milk is rapidly cooled and kept under 50° F., certain fermentative changes which are ordinarily stopped by lactic-acid fermentation increase in activity, owing to the destruction of lactic-acid bacilli by the pasteurization. (4) That pasteurization, by preserving unclean milk for some time, may induce the producers to furnish dirty milk, discourage rigid cleanliness, and promote carelessness on the part of the producer who relies entirely on the pasteurization to preserve the milk. (5) That the pasteurization furnishes a 'purified' milk instead of a 'pure milk.'"—(Price's *Hygiene and Sanitation.)*

5. *Formaldehyde* is a good surface disinfectant, has poor penetrating qualities, does not destroy fabrics and injure objects, and is non-toxic. *Sulphur dioxide* damages textile fabrics, tarnishes metal objects, and is very poisonous.

To disinfect a room by formaldehyde: (1) By Trillat's apparatus, which "allows the solution of formalin to flow in a fine stream through a copper coil heated to redness by a flame beneath, and the gas and vapor passing directly into the room. The apparatus may be operated outside of a room, and the amount of gas liberated depends directly upon the strength and quantity of the solution evaporated. (2) In Schering's method the solid paraform is heated in a receptacle over an alcohol lamp, and is especially valuable in disinfecting small rooms, closets, etc. (3) The cheapest and most common form develops the gas directly by the oxidation of methyl alcohol, the vapors of the latter passing over and through tubes or coils of heated metal. The amount is uncertain and results indefinite."—(Gould and Pyle's *Cyclopedia of Medicine and Surgery.)*

To *fumigate by sulphur dioxide:* For each 1,000 cubic feet of space, three pounds of sulphur are burned, care being taken to prevent accidents. In all cases all apertures and crevices of the room should be closed, all closets, drawers, or other receptacles opened; and after the fumigation the room should be well ventilated and thoroughly cleansed with a solution of corrosive sublimate.

6. *Sources of impurities in air:* Expiration of human beings and animals, combustion, manufacturing processes, dust, walls of rooms and houses, excreta from human beings and animals, decomposition products. The chief danger to health consists in the increase of carbon dioxide, the presence of crowd-poison, dust, irrespirable gases, and various bacteria.

7. The sources of contagion in typhoid fever are food, milk, water, fingers, and flies, or anything that has been in contact with the excreta of a typhoid patient. Typhoid fever is preventable. When the municipal authorities do not consider it their duty to supply pure water, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food; flies should be kept out of the house as far as possible by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

8. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic microorganisms. Immunity may be either natural or acquired.

Natural immunity is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The conditions which give immunity are: (1) a previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Examples: The rat is *naturally immune* to anthrax; the white mouse is *naturally immune* to infection with bacillus mallei. *Acquired immunity* is seen in the immunity from smallpox after vaccination, or after having suffered from an attack of the disease.

9. By the tuberculin test.

10. *Diseases prevalent in school children. Skin:* Pediculosis, scabies, ringworm. *Respiratory:* Bronchitis and bronchopneumonia. *Spine:* Scoliosis, kyphosis, and lordosis. *Digestive:* Constipation, gastritis, anorexia, diarrhea. *Throat:* Adenoids, tonsillitis, hypertrophied tonsils. *Eye-strain* is shown by pain in the eye when used for reading or near work, the type seems blurred, and the letters run together; the eyelids twitch; the eyes smart and "run water," and may appear red and congested; headache, and the reflex symptoms are present. The eyes should be examined and proper glasses provided. *Adenoids* are detected by feeling them in the nasopharynx. *Trachoma* is detected by inspecting the inner conjunctival surface of the eyelids and finding the same rough and granular. *Infectious catarrhal conjunctivitis* is diagnosed by finding with the microscope the Koch-Weeks bacillus in the yellowish discharge.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SURGICAL CLINICS OF JOHN B. MURPHY, M.D. Vol. 1, No. 4 (August, 1912). 154 pages; illustrated; paper; price $8.00 per year. W. B. Saunders Company, Publishers, Philadelphia and London.

PHARMACOLOGY. By MAURICE VEJUX TYRODE, M.D. Second Edition. 228 pages; cloth. P. Blakiston's Son & Co., Publishers, Philadelphia.

PRACTICAL THERAPEUTICS. By HOBART AMORY HARE, M.D., B.Sc. Fourteenth Edition. 984 pages; illustrated with 131 engravings and 8 plates; cloth; price $4.00. Lea & Febiger, Publishers, Philadelphia and New York.

MATERIA MEDICA AND THERAPEUTICS. By REYNOLD WEBB WILCOX, M.A., M.D., LL.D. Eighth Edition. 832 pages; cloth; price $3.00 net. P. Blakiston's Son & Co., Publishers, Philadelphia.

MICROBES AND TOXINS. By Dr. ETIENNE BURNET. 316 pages; illustrated; cloth; price $2.00. G. P. Putnam's Sons, Publishers, New York and London.

Miscellany.

Problems of Sex and of Marriage.—Probably no other book has ever been written which has attacked these problems with such profundity of knowledge and with such a pleasing combination of candor and delicacy as has the widely read and discussed volume on "Love and Marriage," by Ellen Key. Without endorsing all of this writer's ideas on questions that lie at the foundation of modern civilization, the physician will find that many of her conceptions coincide with his own judgment as to certain phases of life with which he is brought intimately in contact. In these days when it has become a fashion to advocate the teaching of sex-hygiene to the young, it is refreshing to note that there is at least one who would seek to curb the sex impulse not by pointing out the pathological dangers of indulgence, nor by a strict appeal to moral precepts, but by showing that "no obstructing of appetites, and only their release in other directions can really purify them." In addition to the powerful influences of heredity and social custom, there are other important factors that tend to control the sexual instinct. All of these expedients are enumerated as follows: "Before all, that of acquiring the instinct of chastity from parents; of being strengthened and protected from childhood against the dangers of callousness as well as those of softness; of being instructed in a refined and gentle way of the great purpose and great dangers of sexual destiny; of receiving impressions through public opinion of the possibility of self-control and its importance to the happiness of the individual himself and of the race; of avoiding the abuse of means of enjoyment, especially of intoxicating liquors, which both directly and indirectly weaken the will-power in the case of sexual, as of all other kinds of temptation. It is beyond question that noble sport, dancing and games—and they are only noble when practised finely and worthily, with the mind as well as the body—are a means of replacing and controlling the sexual instinct. Equally certain is it that bodily and mental labor, whether undertaken independently or as a participation in some form of social endeavor, is important as occupying and consuming the sexual powers in a substituted form. All genuine artistic enjoyment is in the highest degree important for the ennobling of sexual life."

Those who are enlisted in the cause of eugenics will find inspiration in the words: "Religion, poetry, art, and social custom have collaborated to elevate the racial feeling into love. They ought now to collaborate again to make the racial feeling conscious in love. The altars that the ancients built to the divinities of procreation must be rebuilt. Not for men and women to assemble around them in frenzied orgies, in the red glow of sunset, but in the golden light of the morning and the joy of creative day. Family feeling, ancestor-worship, pride of pure blood will regain, in a new sense, their decisive power over emotions and actions."

The Enema in the Eighteenth Century.—In France during the seventeenth and eighteenth centuries the enema syringe was the symbol of medicine. The august body of Louis XIV was washed out by means of it some thousands of times, and it is recorded of a royal duchess that she had the *remède,* as it was politely called, furtively administered to her even in the presence of the Court. It was used by everybody who could afford it, and it was a considerable source of income to the apothecaries. Naturally it did not escape the keen eye of Molière, who introduces it several times. He represents M. de Pourceaugnac being pursued with the instrument by a number of apothecaries, assuring him that it is benign, and in the ballet which concludes the *Malade Imaginaire* the apothecaries carrying the emblem play a conspicuous part. There is a curious record of an action brought in 1746 against a canon of Troyes, François Bourjeois, by what may be called a nurse specialist in the administration of enemas. This lady, who had the very appropriate name of Etiennette Boyeau, brought an action for recovery of moneys due to her for the innumerable enemas she had given the patient. As he would not pay, she put her case into the hands of an advocate named Grosley. His pleading, which is given in French memoirs in all seriousness but which reads like an elaborate jest, set forth that the canon had for some time been "vexed by a heated state of the viscera of that enormous acrimony which causes the generative parts to be extravasated." (Doubtless the writer meant piles.) Having consulted his physician, the canon was ordered the frequent use of "a kind of lenitive commonly known under the name of clyster." Etiennette Boyeau, who was in high repute for her skill in the administration of that remedy, was called in, and she attended on the canon two whole years, officiating at least once, sometimes as often as six times, a day. But, though she served him well and her fee was small, she could get no money out of the canon. "Three hundred times, at the most interesting moments and in the most supplicating position, she begged him to relieve her needs, without his allowing himself to be softened." At length, in 1746, she brought an action against him. In the pleading it is stated that "the Sieur Bourjeois took at least one enema a day and often six, thus taking on an evarage three enemas a day, giving a total of 2,190 enemas, which at 2 sols 6 deniers make up the big figure of 273 livres 15 sols. Etiennette consents to reduce the total number of enemas to 2,000, and to reduce her bill to 150 livres instead of 273 livres 15 sols." The canon resisted, but at last, fearing the publicity of a law court, he paid up.—*British Medical Journal,* September 28, 1912.

Seems Unlikely Just Now.—In spite of the present drift of the current against the horse we are inclined to believe that the optimistic writers are correct, and that in due time the horse will come trotting triumphantly down the magnificent turnpike of the future, more beautiful, more highly prized than ever, and that he will take his important place in the life of the world to minister to man's pride and pleasure in the utilities and ceremonials of the day.—*Motor Car.*

Why Tires Do Best on Stale Air.—The less oxygen a tire gets inside it the better, according to the Michelin tire expert. The reason is that rubber, while it is practically airtight, is not perfectly so, the air gradually filtering through. Of the two principal gases which compose the air—oxygen and nitrogen—oxygen diffuses through the rubber the faster, so that as time goes on the percentage of oxygen may fall quite low. This explains why a new tire has to be inflated several times before it holds air without any noticeable loss. As long as the original air remains in the tire each inflation increases the proportion of nitrogen and thus the loss by diffusion becomes smaller. This diffusion is responsible, no doubt, for the large proportion of cars which run on underinflated tires. Of the cars which stop at the Michelin factory fully 50 per cent. run on underinflated tires. A tire may seem hard and tight, but diffusion may lower the air pressure by as much as ten pounds. The only way to be sure of obtaining the proper pressure is to use a tester, and use it not only when inflating, but periodically—say, once a week.—*Automobile Topics.*

SOME STUDIES IN FAMILY HISTORY.*

By BRANDRETH SYMONDS, A.M., M.D.,

NEW YORK.

CHIEF MEDICAL DIRECTOR, THE MUTUAL LIFE INSURANCE COMPANY OF NEW YORK.

In reviewing the medical aspects of life insurance during the past year, the most important circumstance is that the Medico-Actuarial Mortality Investigation is beginning to bear fruit. The first fasciculus which has been sent to all of the companies contains the new mortality table and new average tables of weights for men and women. This average table of weights for men does not differ appreciably from the one prepared in 1897 for this Association by Dr. Geo. R. Shepherd,[1] except in the ages below 25. In these younger ages Dr. Shepherd did not have sufficient material, and he lumped them all together into one age-group, 15 to 24. The result was that in the ages below 20, his weights were entirely too high. Also he was lacking in data in the extremes of height. Taking it altogether, however, the new average table for men has added but little to our previous knowledge.

The new average table for women differs slightly from the ones prepared by Dr. F. S. Weisse[2] and Dr. O. H. Rogers.[3] Their tables show differences from the new table of two pounds, or less, usually; in many cases they coincide. It can be seen that there is no substantial difference between the average tables which we already had, and this contribution from the Medico-Actuarial Investigation. We must remember that these tables represent the average weights of selected insurance risks in this country and Canada, clad and shod at the time of the examination.

For many years I have felt that the average weight in the younger and in the older ages does not coincide with the weight showing the lowest mortality at those ages. In 1908,[4] I stated that weights a little above the average gave the lowest mortality in the younger ages, and weights a little below the average gave the lowest mortality in the older ages. You will remember that Dr. Rogers demonstrated this most beautifully two years later to the Association by a model showing the range of mortality as affected by physique, according to the experience of The New York Life.

In view of the fact that the Medico-Actuarial Investigation will soon publish the results of the mortalities of some 900 classes of weights, should we not take advantage of this to determine a table of weights graded according to the best mortality? Ought not the association take official notice of this fact and stamp such a table with its approval by referring the matter to a committee who will prepare it? By so doing, the life insurance companies will then have a table of heights and weights which will be a standard guide on the determination of the proper physique. I am confident that such a table can be prepared and I recommend that a committee be appointed for that purpose.

The new mortality table adopted for the Medico-Actuarial Investigation is substantially different from any mortality table heretofore published, especially in the ages below 50. In these ages, the mortality rate is generally lower than in other tables, whether select or ultimate. Furthermore, the ultimate rate is reached in the fifth year of insurance, which is earlier than usual. Both of these conditions seem to be due to two factors:

1. The decided improvement in the general mortality of the country, especially in the younger ages, owing to a marked decrease in the infectious diseases, both acute and chronic.

2. A considerable improvement in the methods of selection in our life insurance companies, whereby the sub-standard cases are properly classified. Doubtless, this last factor is very important in making the ultimate rate so early. It is also a factor in reducing the general rate of mortality, but here a more important item is the improved sanitary condition of the country.

In the ages above 50, the mortality has not improved appreciably in later years; in fact, the issues of 1901-1908 show a mortality of 93 per cent. in the ages over 60 as compared with a mortality of 91 per cent. in the same ages for the issues of 1885-1892. This deterioration has occurred in spite of greater care and skill in examining. In the earlier period, many companies did not require a chemical examination of the urine in all cases, a microscopical examination was rarely made, the blood-pressure was never taken, and the diagnostic training of the medical examiner was inferior as compared with the later period.

This fact was well set forth in a paper[5] read at the twenty-first annual meeting of this association by Mr. James D. Craig, Assistant Actuary of The Metroplitan Life. A careful study of his paper shows that the mortality has been substantially lowered among insured lives in the years before fifty, but raised in the years subsequent to fifty.

TABLE A

Mortality of Males in England and Wales per 1,000 in Successive Decennia

Ages	1841–1850	1851–1860	1861–1870	1871–1880	1881–1890	1891–1900
All Ages	22.37	22.04	22.48	21.64	19.79	19.32
0–	71.20	72.43	73.47	68.42	61.61	62.71
5–	9.16	8.51	8.19	6.71	5.35	4.31
10–	5.12	4.88	4.48	3.71	2.95	2.45
15–	7.05	6.69	6.19	5.25	4.32	3.79
20–	9.50	8.83	8.48	7.36	5.73	5.06
25–	9.94	9.57	9.94	9.34	7.77	6.76
35–	12.85	12.48	13.48	13.80	12.40	11.50
45–	18.22	17.96	19.26	20.07	19.37	18.95
55–	31.81	30.85	33.14	34.88	34.71	34.95
65–	67.51	65.33	67.12	69.72	70.46	70.39
75 and upwards	168.56	165.40	165.46	169.30	162.67	160.09

*The address of the President at the twenty-third annual meeting of the Association of Life Insurance Medical Directors of America, Oct. 9, 1912.

This phenomenon is present in other countries as well. The following table A shows how it has affected the male population of England and Wales:

You will notice that the mortality among males has improved in all ages below 45 and almost uniformly. Beginning with age 45, however, it has deteriorated in all later age-groups except the last. In each of the age-groups 55- and 65- the mortality in the decade 1891-1900 was 3 per 1000 larger than in 1841-1850, fifty years earlier. The difference is even more marked if we compare 1891-1900 with the decade 1851-1860, for here the mortality in the age-group 55- is 4 less per 1000 and in the age-group 65- it is 5 less per 1000 than in 1891-1900. After age 75, the mortality has improved, but this has no great interest for us insurance men.

It seems then to be established that there has been an increase in deaths sufficiently large to cause an increased mortality after fifty years of age. This increase is due to degenerative diseases and has occurred in spite of all our improvements and our better knowledge of disease. Even though our knowledge of zymotic diseases and our skill in preventing and overcoming them has increased more rapidly than our means of combating the degenerative diseases, we ought to have as great success in treating the latter as our fathers did. Some explanation then must be found to account for the increased mortality after fifty years of age due to these diseases.

1. Syphilis may be a little more frequent than formerly, though I doubt it. It is treated with much more thoroughness and certainty and in any case is a very small factor.

2. The annual consumption per capita of distilled liquors in this country is just one-half the amount fifty years ago.[7] The annual consumption per capita of malt liquors, however, has increased from 5 gallons to 20 gallons. According to Mr. Emory McClintock,[9] beer is more harmful than whiskey when measured by its alcoholic content. Alcohol figures largely in the causation of many degenerative diseases and the increased consumption of malt liquors may be a factor in the increased mortality from these diseases.

3. Tobacco, tea, and coffee are used more freely than formerly,[7] but their relation to disease has not been established. It may be that deaths from heart disease are hastened by their use, thereby indirectly increasing the mortality from this. Tobacco is accused also of causing arteriosclerosis, though this theory is not yet accepted by the medical profession. In any case, they must be regarded as small factors in the causation of these diseases, and altogether they seem insufficient to account for more than a small part of the increased mortality.

4. A great deal has been said about the nervous strain of our modern complex life. Undoubtedly, insanity has increased, though part of the increase is due to its prompter recognition and the nearly universal treatment in institutions, by whom all the cases are accurately reported. It is not a frequent cause of death, however. In 1910 in the registration area of the United States, including more than one-half of the population of the continental United States, there were recorded 588,093 deaths among those of five years and upwards, of which 4605 were due to all varieties of mental alienation. This is less than 0.8 per cent. of all deaths of five years and over, and insanity, therefore, is not an appreciable factor in increasing the death rate after 50.

When we come to study the deaths from other nervous diseases, we find some very instructive facts. If there is any truth in the theory that the hurly-burly and worrying pressure of our modern business life lowers vitality and increases mortality, it should be capable of demonstration in the deaths due to diseases of the nervous system. That system would naturally be the first one to break down under such a strain. If there be any such strain it should show itself in the cities much more than in the rural districts, for life is undoubtedly more placid and less exciting in the country. Now, the registration-states in 1910 contained 47,610,525 population, of which 25,047,702 (53 per cent.) lived in cities of 10,000 and upwards, and 22,562,823 (47 per cent.) in rural districts.

The following table shows the actual number of deaths and the rate of mortality per 100,000 of population in each of these areas for several of the degenerative diseases:[8]

TABLE B

Mortality in Cities and Rural Parts of the Registration-States from Different Diseases

	Cancer	Diabetes	Organic Disease of the Heart	Nephritis, Bright's Disease	Cerebral Hemorrhage and Softening
Cities.....	20,505 81.4	4,232 16.8	36,618 145.4	28,031 111.3	18,537 73.6
Rural Parts ...	15,859 70.1	3,050 13.5	31,162 137.8	17,319 76.6	18,672 82.5

This table shows that the cities gave a higher mortality rate than the country in the case of cancer, diabetes, organic diseases of the heart and Bright's disease. When it comes to cerebral hemorrhage and softening, however, the mortality rate in the cities is distinctly lower than in the country. In truth, this theory that nervous strain causes an appreciable increase in mortality has no real standing. It should be cast out into the lumber-yard of discarded and rejected ideas. Probably, the former times have seemed to man at all epochs to be "the good old days." Doubtless when our forefathers began to live in caves and lost their tails through disuse and atrophy, they looked back with regret at "the good old days" when their fathers built nests in the trees. They told each other that the nervous strain of dodging saber-toothed tigers and cave-bears was too much, and that they must go back to the simple life of the tree-tops.

5. The great increase in our city population, both actual and relative, has materially changed our habits with regard to muscular exercise. The multiplication of athletic clubs of all sorts and the increase of athletic games and competitions do not affect the great mass of city people, for only a very small percentage are anything but spectators. In city life very little exercise is taken by the average man, except among the manual workers who are not apt to seek ordinary insurance, and the facilities of transportation are so great that walking is cheerfully avoided by everybody who has five cents. These conditions are almost reversed in country life. In the matter of physical exercise then we can say that there has been a great change among the people of this country in the past fifty years. Furthermore, this condition seems liable to increase rather than diminish. Lack of exercise may be a factor of some value in the causation of degenerative diseases which are usually found in those above fifty.

6. It has been said that these degenerative diseases are largely due to overeating and that this has increased in the past fifty years. There is much truth

in the statement that overeating is an important factor in the causation of arteriosclerosis, Bright's disease, apoplexy, heart disease and other degenerative diseases. A study of the causes of death among overweights[4] shows this conclusively. There is grave doubt, however, whether overeating has increased during the past fifty years. If we compare the menus of the public dinners prior to the Civil War with those of the present day, the latter are much shorter and simpler than the former. In private life too our grandfathers were lustier trenchermen than their degenerate grandsons, if we can believe what they have told us. The truth seems to be that we now eat as much as we can stow away, and so did they, and perhaps their capacity was a little greater than ours.

7. A factor of great importance in causing the increased mortality after fifty is the unquestioned decrease of mortality in the earlier ages. Up to about one hundred years ago the infectious diseases, both acute and chronic, acted as filters for the elimination of human weaklings in infancy, childhood, and young adult life. Undoubtedly they also killed a good many robust specimens in the process, but the survivors were left without harmful sequel and with comparative immunity from subsequent trouble. For more than a century, in fact since Jenner demonstrated the value of vaccination, the human race has been changing this natural method of self-improvement. In the past thirty years since Koch discovered the tubercle bacillus, we have rid ourselves largely of nature's racial filters. A great many now reach adult life who would formerly have been killed before that time. Many of these have no capacity for living a long life. Perhaps if the same minute care were taken of them throughout their life as in their childhood and youth, they might survive to a decent old age. The lusts of the world, the flesh, and the devil, the need of self-support, the providing for a family, and the competition with robust vitality prevent any such care. They die before attaining old age of some disease which would not have proved fatal in a more resistant individual.

No statistical proof can be given of this theory, and it can only stand by the exclusion of other possible causes. We cannot demonstrate that a man dying in the forties or fifties would have died in childhood or youth from some zymotic disease if he had happened to catch it then. But the combination of this with the increased consumption of malt liquors, tobacco, tea and coffee, and the increasing lack of exercise seems to be sufficient to produce the increase in the death-rate after fifty years of age. Furthermore, the theory explains the acknowledged facts without any strain, and will bear close criticism.

For us Medical Directors whose business it is to secure a favorable mortality for our companies at all ages of life, the next step is to ascertain how we can pick out these individuals in apparent health, but without capacity for long life. This part of the problem will be difficult, for no reliable tests are now apparent. The Medico-Actuarial Mortality Investigation will doubtless show come conclusions of value from a study of the medical impairments.

Perhaps, for instance, it may show that neurasthenia is the expression of an organic weakness tending to shorten life, though not amounting to a disease. We have been taught that neurasthenics live forever, but the eternity may be due merely to their everlasting nagging and fretting and their insistent selfishness which demands constant care and attention from others. Against this idea is the fact that the Jews are both neurasthenic and long-lived.

The Specialized Mortality Investigation showed that functional cardiac conditions, such as an intermittent, irregular or frequent pulse, were much more serious after forty years of age than before. Perhaps the Medico-Actuarial Investigation with its lower death-rates in the younger ages will show that these conditions must not be disregarded in the young.

Perhaps we will learn more exact rules regarding the significance of arterial hypertension and hypotension at different ages.

Some two years ago, *consule Willardo*, while thinking over this question of the increased death-rates in ages over 50, it occurred to me that it might be possible to determine whether different grades of parental longevity appreciably influenced the vitality of the offspring. We were just beginning to write the cards for the Medico-Actuarial Investigation and the opportunity was at hand. The greatest difficulty lay in defining a long-lived family history, and I finally had to break this up into three groups, with a definition for each group. Definitions for an average family history and a short-lived family history gave no difficulties. Following are the definitions of these various groups which will hereafter in this paper be called symbols:

Symbol A—Both parents reached 70.
" B—One parent and two grandparents reached 70—other parent living.
" C—Both parents living below 70, and three grandparents reached 70.
" D—All cases between the above and E are to be classed as D.
" E—Both parents dead below 60.

As you will see, these symbols are arranged in the order of definite longevity of the parents, for I am sceptical regarding the ages of grandparents as furnished by applicants for life insurance. However, in Symbols B and C we had to refer back to grandparental ages, and this naturally raises a question as to the validity of these symbols. One circumstance tends to show that the information contained in Symbols B and C is reasonably reliable. For the nine years during which the family symbols were noted, the entire number of applications to the Company, which were studied for the investigation, amounted to 320,000. Of these only 167,564 (52 per cent.) could be classified under the various symbols. In some cases the ages of the parents did not permit the risks to be classified. In many cases, however, the applications studied in this investigation failed to give the history of the grandparents in sufficient detail to enable us to classify them under the proper symbol. Such indefinite terms as "old," "very old," "about 70," etc., were carefully excluded and only positive statements as to age were accepted.

With regard to Symbol D, the lower limit is not easy to define but usually one parent must have reached 60. The upper boundaries varied a good deal. It might be that one parent had attained 70 and the other parent was living below 70, but only one grandparent instead of two had reached 70. The case would then be classified in D and not in B. Similarly both parents might be living below 70, but less than three grandparents had attained 70. The case would then be classified in D and not in C. Both of the cases just cited might have the potentiality of long life, but this fact could not be decided until some years later. Symbol D therefore may

contain some cases which in time would show a long-lived family history and the fact must be remembered when we come to study the mortality of the various symbols. Outside of these cases, Symbol D contains those applicants, both of whose parents if dead had attained 60, but neither of whose parents had passed 70.

The definitions of Symbols A and E are so exact that no further explanation of their composition is needed.

The nine years of the companys business, 1891-1899, constituted the period during which we noted these facts regarding parental longevity. This period covers the middle point of the Medico-Actuarial Investigation, though lying mostly anterior to that point both as regards years of issue and volume of business. During the entire period, medical selection by the Company was homogeneous and the conditions of the policies issued did not vary greatly. The great majority of applications were for limited payment life policies and practically no term insurance was written. In order to secure complete homogeneity in this study, the following measures were taken.

In the first place, all cases showing any medical impairments were discarded. Likewise all questionable or hazardous occupations, including the entire 68 kinds called for by the Medico-Actuarial Investigation were discarded. These two amounted to 47,938. Then those cases belonging in the overweight build-groups 3, 4 and 5, amounting to 2,672, were discarded. Then those cases belonging to the light-weight build-groups 8 and 9, amounting to 364, were discarded. As a result of these measures, the original number of entrants, 167,564, was reduced to 116,590. This mass seemed to be quite homogeneous in most respects, for it consisted of white men residing in the United States and Canada, without any medical impairments in their personal or family history, following favorable occupations, and whose weight came within the limits set forth in the following table:

TABLE C

Height	Weight	Height	Weight
4 feet 9 n.	between 94 and 157	5 feet 7 in.	between 114 and 190
4 " 10 in.	" 95 and 158	5 " 8 in.	" 117 and 196
4 " 11 in.	" 96 and 160	5 " 9 in.	" 121 and 202
5 " 0 in.	" 97 and 162	5 " 10 in.	" 125 and 209
5 " 1 in.	" 99 and 165	5 " 11 in.	" 130 and 216
5 " 2 in.	" 101 and 168	6 " 0 in.	" 134 and 224
5 " 3 in.	" 103 and 171	6 " 1 in.	" 139 and 232
5 " 4 in	" 105 and 175	6 " 2 in.	" 144 and 240
5 " 5 in.	" 107 and 179	6 " 3 in.	" 150 and 250
5 " 6 in.	" 110 and 184	6 " 4 in.	" 155 and 259
		6 " 5 in.	" 162 and 269

This mass of material was then divided into five classes, indicated by the Symbols A, B, C, D and E, according to the definition above. The expected mortality was calculated by the Medico-Actuarial Select Mortality Table, the period of observation ending with the anniversary of the policy in 1909. It must be understood that we as well as the Medico-Actuarial Mortality Investigation are working on applications, strictly speaking, and not on lives or policies in the narrower definitions of these terms. In this we follow the lines laid down for the Specialized Mortality Investigation. Even in a single company there are often several applications on one life, but for the purpose of mortality statistics, this factor can be disregarded. Tables 1, 2, 3, 4 and 5 show the results in all five symbols.

A study of these tables shows:

1. The percentage mortality of the Symbols A, B and C, which are the ones possessing a long-lived family history, is distinctly good, being 87 per cent. in A, 86 per cent. in B, and 86.5 per cent. in C.

The marked agreement of these three symbols in percentage mortality confirms the opinion that all three are composed of men who have a long-lived family history. It also demonstrates that the grandparental history was accurately given by the men composing B and C.

2. Symbol D is inferior, the percentage mortality being 92 per cent. This symbol is composed of those with an average family history, neither long-lived nor short-lived, and naturally contains the largest number of entrants. As explained before, this symbol contains also a certain number who have the possibility of a long-lived family history, though that fact could not be demonstrated at the time of the examination. This factor probably tends to lower the mrtality a little. While the mortality is higher than in A, B and C, it is still good, being substantially below 100 per cent.

3. Symbol E shows a percentage mortality of 110 per cent. This symbol is composed of those with a short-lived family history, both parents having died before 60.

The difference between a long-lived and a short-lived family history is only 10 years in both parents, they being above 70 or below 60, but the latter gives a mortality 23 points larger than the former. It is nearly one-quarter better to be born in a long-lived family.

All of the above results have been obtained from homogeneous material, differing only in the matter of family longevity. You will recall that in order to secure this homogeneity, I had to eliminate a number of discordant elements. The first discards consisted of those cases which showed a medical impairment in the personal history or in the physical condition, or which belonged in one of the 68 questionable occupations called for by the Medico-Actuarial Mortality Investigation. Then the overweights, whose weight was above the scale already given, and the underweights, who were below the scale, were eliminated. The percentage mortality in these three sets of discards is set forth in the following table. In order to make comparisons, I have also inserted the percentage mortality of the original material before anything was eliminated. This amounted to 167,564 entrants, showing a total percentage mortality of 98.9 per cent.

TABLE D

ISSUE OF 1891 TO 1899—EXPOSURE OF 1891 TO 1909
Ratio of Actual to Expected Deaths

Symbols	Original Entrants	First Discards	Over-weights	Under-weights
A.....	94.6	102.6	143.6	111.2
B.....	97.1	120.6	169.7	.....
C.....	88.7	94.1	105.3	111.0
D.....	98.8	114.0	116.9	116.0
E.....	123.0	139.7	155.7	666.0
Total.....	98.9	112.8	130.8	123.5

A study of the above table shows that:

1. The original material was quite well selected. Not enough importance, however, was given to a short-lived family history as an impairment, as evidenced by a mortality of 123 per cent. in E.

2. The first discards show that a long-lived family history is able to carry considerable impairments or questionable occupations without harm, except in symbol B. The mortality of 121 per cent. here shows either that too big a burden was attempted on

the strength of the family history, or that the history of grandparental longevity was not reliable. An applicant is easily tempted to bolster up a weak point in his personal record by an appeal to his ancestors. The mortality in Symbol D shows that even an average family history will bear some impairment. A shortlived family history, however, will not stand any as shown by a mortality of 140 per cent. in E. It is a substantial impairment in itself.

3. The overweights were not numerous, amounting in all to 2,672, only about 1.6 per cent. of the original entrants. Nearly one-half occurred in the long-lived family history group, and the burden was rather too heavy, as shown by a mortality of 141 per cent. for the three symbols A, B, and C. A short lived family history can evidently bear very little in the line of overweight, for the mortality there was 156 per cent. Although the fact does not appear in this table, it is important to know that the mortality among the overweights was much higher in all five symbols from the age of 40 upward than it was in the earlier ages.

4. The underweight mortality is not very bad, but the deaths are too few in all symbols for any definite deductions.

In making this study, no attention was paid to the causes of death among parents or grandparents, for I am frankly skeptical as to the value of this information as found in the examinations of applicants for life insurance. We only excluded those who showed among parents, brothers, or sisters, one or more cases of tuberculosis, or two or more cases of apoplexy and paralysis, or of diabetes, or of cancer, or of insanity, or of epilepsy, or of heart disease. Remembering this limitation of our material, it is of interest to note the causes of death among the offspring of these various grades of family history, or in other words, among the policyholders whom we have been studying.

Before entering upon this analysis, it must be premised that the mode of exit among human beings is considerably influenced by the age at exit, or to put it in other words, that the cause of death depends to a marked degree on the age at death. We expect to find among those dying under 30 a very large percentage of the causes of death to fall under the two heads, acute general diseases "A" and tuberculosis. In fact, under 30 these two in my company amounted to 55 per cent. Conversely, the degenerative diseases are very scarce under 30. After 30 they become gradually more numerous, though still comparatively few until about age 50. During this time the acute general diseases "A" and tuberculosis become less common and after 50 are distinctly rare. There are numerous other factors which help in determining the mode of exit, such as overweight which predisposes to degenerative diseases, and underweight which predisposes to tuberculosis and pneumonia, but we must never forget that the age at exit has a greater influence than any other single factor.

Table 6 shows the causes of death in each of the symbols.

A study of this table shows us that:

1. In Symbol A we find that acute general diseases and tuberculosis account for 13.3 per cent. This low rate is largely due to the fact that only 4.5 per cent. of the entrants were below age 30.

2. In Symbol B 31.1 per cent. and in Symbol C 36.5 per cent. of the deaths were from tuberculosis and acute general diseases, although the percentage mortality of each of these symbols was a shade better than in Symbol A. The much greater frequency of these diseases in B and C arises from the fact that 32 per cent. of the entrants in B were under 30 and 70 per cent. in C.

3. In Symbol D 27.6 per cent. of the deaths were from these two sets of causes and the entrants under 30 amounted to 47 per cent.

4. In Symbol E although the entrants under 30 amounted to 31 per cent only 22.5 per cent. of the deaths were from these two sets of causes. This was unexpected, for on account of the higher mortality in this symbol the deaths occurred earlier than in A. If the percentage of entrants under 30 had been the same in E as in A, the total deaths from these two causes would have amounted only to 3.4 per cent. in E. The actual number of those who died before reaching age 30 was too small in both A and E to admit of more elaborate analysis.

When the degenerative diseases were analyzed, it was found that the deaths from each were too few to make any positive deductions. We therefore added together the deaths from these diseases, which are usually regarded as typical degenerative diseases —cancer, diabetes, cerebral apoplexy and paralysis and softening, organic disease of the heart, anginapectoris, arteriosclerosis, nephritis, and Bright's disease. This table shows the results of each symbol, divided into those who died before 50 and those who died at 50 and over. The percentage is in terms of the deaths from all causes incurred in each symbol in the corresponding age-period.

TABLE E

Deaths from Degenerative Diseases

	Under 50		50 and Over	
	Number	per cent.	Number	per cent.
Symbol A	99	27.1	397	52.8
" B	55	20.6	25	50.
" C	104	14.9	19	59.5
" D	353	17.6	409	50.3
" E	76	22.	116	51.7
Total	687	18.6	966	51.6

1. Under 50, 27 per cent. of the deaths in A were from degenerative diseases, and in B 21 per cent. In C the percentage was only 15 and in D 17.6 per cent., but in E it jumps up to 22 per cent. In A both of the parents had attained 70 and in B one parent and two grandparents had reached 70, the other parent being alive below 70. In E, on the other hand, both parents had died below 60. Now the reason for the high proportion of degenerative diseases in A under 50 is the low percentage of tuberculosis and acute general diseases. Those who died under 50 had to die of something, and as the exit by way of tuberculosis and acute general diseases was closed, more than one-quarter of them took exit by way of the degenerative diseases. Practically the same conditions prevailed in E. It is fair to assume for A that nearly all the parents died of degenerative disease and had shown decided resistance to tuberculosis during their lifetime. These qualities seem to have been transmitted to their descendants whom we are studying. I have no data upon which to draw any definite conclusions regarding E, but it is tempting to assume that the marriage of two short-lived people produces offspring who have no resistance to degenerative disease and whose cause of death may be considered evidence of precocious senility.

The Medico-Actuarial Mortality Investigation called for certain family history records as evidenc-

ing possible medical impairments. These constitute the 13 classes from 49 to 61. The 7 classes from 49 to 55 cover tuberculosis in the family. The other family history classes from 56 to 61 cover two or more cases of apoplexy or paralysis, of heart disease, of cancer, of diabetes, of insanity, or of epilepsy. In all cases the term family means parents, brothers and sisters, but does not extend to grandparents or collaterals. Living parents, brothers, or sisters afflicted with one of these diseases are reckoned as if dead from it. While making a record of these classes, we also noted the longevity of the family as a whole, dividing the cases into the symbols A, B, C, D, and E, in accordance with the definitions already given. Here again we found that often the case could not be classified according to longevity, and these cases will be grouped under Symbol X as indeterminate.

When we came to analyze these classes, we found that the material was rather scanty save in 53 and 55. In these two the material was sufficient to justify an elaborate analysis, but in the others we have had to content ourselves with what subdivisions the material permitted. In all classes the same conditions were observed as in the untainted family history symbols. Only white men were included, and the 68 occupations called for by the Medico-Actuarial Mortality Investigation were discarded. In one respect, however, the composition of these classes differed from the ones we have already discussed. The year of issue began with 1885 instead of 1891, and extended to 1908 instead of ending with 1899. The period of observation terminated in both cases with the anniversary of the policy in 1909.

So far as medical impairments are concerned, those prior to number 49 were eliminated and these cover all the more important and more common ones. Those medical impairments which are named in the Medico-Actuarial list following the family history classes were included, but these are very infrequent, with the exception of hernia. In the Mutual Life, policyholders with hernia were always required to wear a truss, so the influence of this factor may be disregarded.

Let us then take up for consideration Medical Impairment Class No. 53, one brother or sister dead of tuberculosis, or afflicted with it. In studying tuberculosis in the family it seemed to be necessary to take the weight of the entrants into consideration, and each symbol was divided into the lighter weights and the heavier weights, according as they fell above or below the following scale:

Height	Weight	Height	Weight
4 ft. 9 in.	119	5 ft. 9 in.	153
4 ft. 10 in.	120	5 ft. 10 in.	159
4 ft. 11 in.	122	5 ft. 11 in.	164
5 ft. 0 in.	123	6 ft. 0 in.	170
5 ft. 1 in.	125	6 ft. 1 in.	176
5 ft. 2 in.	127	6 ft. 2 in.	183
5 ft. 3 in.	130	6 ft. 3 in.	190
5 ft. 4 in.	133	6 ft. 4 in.	197
5 ft. 5 in.	136	6 ft. 5 in.	205
5 ft. 6 in.	140		
5 ft. 7 in.	144		
5 ft. 8 in.	149		

This scale is the dividing line between build-groups 0 and 6. Build-group 0 runs about 10 per cent. above this scale and build-groups 1, 2, 3, 4, and 5 are progressively heavier in about the same proportion. Build-group 6 covers about 10 per cent. below the scale, and build-groups 7, 8, and 9 are progressively lighter in about the same proportion. This dividing scale is above the average weight of men up to age 25, and after that it is below the average weight. Build-group 6 contains a few young entrants who are above the average weight for their age, and build-group 0 containing a few more older entrants who are below the average weight for their age. This raises the question whether build-group 0 is properly classified among the heavier weights. So far as a tubercular family history is concerned, I am convinced that it is properly placed there, for the influence of weight in this impairment diminishes rapidly after 30, as I will show later.

I made but one actual test of build-groups 0 and 6, and this showed a mortality under 30 of 133 per cent. for 6, and 83 per cent. for 0. These results are doubtless exaggerated on account of the small number of deaths in the test, but they indicate the proper place for build-group 0.

Tables 7, 8, 9, 10, 11, 12, and 13 show the results in each of the symbols and in the two subdivisions of each symbol:

1. The class as a whole shows good results, the total mortality being only 95 per cent. It is quite high in the ages below 30, but distinctly good above 40.

2. Symbol X, in which the family record is indeterminate, though not containing cases with a demonstrably long-lived family record, is also good, the mortality being 96 per cent.

3. Symbol A, where both parents had attained 70, is excellent, the mortality being 78 per cent.

4. Symbols B and C, both supposed to be long-lived, show a mortality of 95 per cent., nearly the same as Symbol D, which represents an average family history. This arises partly from the fact that B and C contain a large proportion of younger entrants. B has 80 per cent. of its entrants under age 40, and C 95 per cent. as contrasted with 71 per cent. in D and 60 per cent. in E. Sixty per cent. of the entrants in C are under age 30 as contrasted with 32 per cent. in D and 21 per cent. in E.

I think this suffices to account for the high mortality in C, especially as nearly two-thirds of these entrants under 30 fell among the lighter weights. In regard to B, we must remember that the definition of this is "one parent and two grandparents reached 70, the other parent living." If less than two grandparents reached 70, the case would have been put in Symbol X. Perhaps some of those applicants misstated the age of the grandparents and thereby transferred themselves from X to B.

I am convinced that the grandparental history as affecting the untainted symbols B and C was correctly given and that when correct it is of substantial value in determining the prospective longevity of an applicant, especially in the younger ages. On the other hand, an applicant's conscience is pretty flexible as regards the ages of his grandparents if he thinks that the addition of a few years there will better his prospects for life insurance.

5. E shows very poor results, the mortality being 133 per cent. The deaths are few, but the result, though exaggerated perhaps on this account, accords with our knowledge of the significance of a short-lived family history.

6. When we come to study the influence of weight, the results are interesting. The total mortality of the lighter weights is 100 per cent. and of the heavier weights 91 per cent.

Table F shows the mortalities in the different age-groups:

TABLE F

	Lighter Weights	Heavier Weights
Under 30	140%	106%
30–39	111%	98%
40–49	79%	81%
50 and over	73%	91%

Under age 30, the heavier weights have decidedly the best of it. The combination of a tubercular brother or sister with build-groups 6 and 7 makes for a high mortality in these ages. It is important to note this, for under 25 years of age build-group 6 contains some who are above the average weight for the age. It also emphasizes the importance of establishing a table of heights and weights in accordance with the mortality and not with the average. From 30-39 the lighter weights still have the worst of it, but they are not very bad and the difference between the two groups is much less. After 40 a tubercular brother or sister seems to be of little consequence, and after 50 the lighter weights have distinctly the better mortality, thereby again drawing attention to the need of a proper table of heights and weights.

In the individual symbols, however, the significance of the weights varies and in B, D, and E the lighter weight mortality is distinctly better than the heavier weight mortality. In all three symbols, however, it seems to depend partly upon the age-composition of the two sets of build-groups. The lower mortality of the older ages in the lighter weights more than compensates for the higher mortality of the younger ages and the converse is true in the heavier weights.

The definition of Medical Impairment Class No. 55 is "one parent dead of tuberculosis." The class was a large one in the Mutual Life like M. I. Class 53, for one case of tuberculosis in the family record has not acted as much of a bar to insurance.

Symbols B and C were practically unrepresented for there were but three deaths in B and one in C, and therefore they have not been analyzed. The entire class and the other symbols, divided into lighter and heavier weights as in M. I. Class 53. are set forth in tables 14, 15, 16, 17 and 18.

1. The class as a whole has been well selected, the total mortality being 94 per cent. This is a trifle better than M. I. Class 53, and nearly every subdivision of 55 shows a similar result. The mortality of the heavier weights throughout is lower than that of the lighter weights.

2. The deaths in A are too few for comment, except that the low mortality accords with our expectations.

3. X with a mortality of 92 per cent. and D with 95 per cent, require no comment, especially as the lighter weights show a larger mortality than the heavier weights in each symbol.

4. E, the short-lived family history symbol, shows a mortality of only 95.6 per cent., less than 2 per cent. greater than that of D, and very much lower than that of 53 E which is 133 per cent. This requires explanation, but before taking it up, I wish to submit the following table which shows the mortality in the lighter and heavier weight sets of the whole M. I. Class 55 at different ages:

TABLE G

Ages	Lighter Weights	Heavier Weights
Under 30	124%	96%
30–39	107%	83%
40–49	76%	88%
50 and over	60%	78%

If you compare this table with Table F you will notice that the results are uniformly lower than in that class, showing that 55 has been better selected than 53, and this is true of all ages and all weights. Perhaps this improved selection in 55 was due to the idea that the hereditary influence of tuberculosis would be more strongly transmitted through a parent than through a brother or sister. Now, the results in the symbols other than E show this stricter selection to a moderate degree only, but in E to a very striking degree. Symbol E contains only those, both of whose parents have died below sixty years of age, and in 55E one of these parents must have died of tuberculosis. That was the pen-picture presented to the Medical Director, and he undoubtedly approved for insurance only those cases which he thought were distinctly favorable. It is not easy in a small class like this to say definitely what were the factors which made for better selection, for we cannot subdivide it further with conclusive results. Let us consider in detail, however, the factors in which 55E differs from 53E.

1. The age composition differs somewhat. Thirty-seven per cent. of the entrants in 55E are under thirty years of age, and only 21 per cent. in 53E. Ordinarily, this would tend to make the mortality in 55E higher than in 53E, but it does not succeed.

2. The weight composition differs a little in the two classes and it is set forth in full detail in the following table:

TABLE H

M. I. No. 53. One Brother or Sister Dead of Tuberculosis. Symbol E

Build Group	All Ages		15–29		30–39		40–49		50 & Over

3	50	1.4	5	.4	22	1.6	15	2.3	8	4.0
4	18	.5	...	...	6	.4	12	1.9	...	...
5	...	...	...	...	...	...	...	...	...	...
6	1322	37.3	600	45.2	494	35.7	185	28.9	43	21.6
7	404	11.4	194	14.6	149	10.8	51	8.0	10	5.0
8	6	.2	4	.3	2	.1	...	...	...	...
Total...	3552	...	1326	...	1384	...	643	...	199	...

In the age-period 15-29 light-weight build-group 7 is larger proportionately in 53 than in 55. In the age-period 30-39, build-groups 6 and 7 are smaller in 53 than in 55. In the age-period of 50 and over the heavier build-groups 1, 2, 3, and 4 are smaller in 53 than in 55. The differences, though, are not marked in any case. It seems hardly possible to ascribe the difference in mortality to them alone for the lighter weights favor 55, but the heavier weights favor 53.

3. Judging by the causes of death, the risk of infection has been about the same in the two classes. In 55E 22 per cent. of the deaths were due to tuberculosis and in 53E 25 per cent.

4. The influence of heredity presumably differs in the two classes, for it is natural to assume that a parent is more potent in this regard than a brother or sister. The selection of the risks in these two

classes was undoubtedly influenced by this idea, though considered by itself, heredity ought to favor 53.

5. Perhaps the family histories in 53E are not reliable. In this class the applicant acknowledges that a brother or sister has died of tuberculosis and that both of his parents have died under sixty, but not of tuberculosis. It may be that in some of these cases one or both parents did die of tuberculosis. If so, the case would properly belong in 51E or 49 E. In these classes the mortality is much higher than in 53 E as will be shown.

The definition of Medical Impairment Class 50 is "one parent and two or more brothers or sisters dead of tuberculosis or afflicted with it." The class was small and naturally contained almost none in Symbols A, B, and C. Tables 19, 20, 21, and 22 show the results in the whole class, and in Symbols X, D, and E.

1. The results in the whole class are fairly good, the mortality being only 106 per cent. Below 40 it is quite bad, 172 per cent., but above that age it is only 86 per cent.

2. X shows a mortality of 67 per cent., D of 105 per cent., and E of 200 per cent., but the number of deaths in each symbol is too few to warrant any conclusions. It is interesting, though, to note that the rise in mortality accords with the fall in family longevity.

3. Theoretically, the class ought to show a much larger mortality than 106 per cent. Doubtless the cases were picked with great care. When the class was divided into build-groups, it was found that the distribution differed greatly from that in 53 and 55. In these the build-group 1, which represents the very moderate overweights, contained 14 per cent., of all entrants, but in 50 it contained 22 per cent. The light-weight build-groups in 53 contained 44 per cent. of the entrants and in 55, 52 per cent. of the entrants, but in 50 only 20 per cent. of the entrants. This weight distribution must be of great influence in determining the low mortality in 50, and with the greater care in selection may suffice to account for it.

The definition of Medical Impairment Class No. 52 is "two or more brothers or sisters dead from tuberculosis or afflicted with it." This class is not very large, and probably contains few with more than two cases of tuberculosis in the family record. Symbols X, A, and D contained sufficient entrants to permit their subdivision into the lighter and heavier weights, but B, C, and E were too small. Tables 23, 24, 25, and 26 show the results of our analysis.

1. The class as a whole is a little inferior, the mortality being 108 per cent., though in the entrants above 50 it is distinctly good. The risks were certainly picked with care, but in spite of this, the mortality in ages below 40 was 142 per cent. The age group 40-49 shows a mortality of 127 per cent. but this is due almost entirely to the heavier weights, who show a mortality of 144 per cent. in this age group, the actual deaths amounting to 55.

2. X shows a mortality of 115 per cent. for the whole symbol. The lighter weights are good, giving only 97 per cent. as against 121 per cent. for the heavier weights. These mortalities go against the rule. Perhaps the irregularity is due to the small number of deaths, or it may be that we attached too much importance to weight as an antidote to the tubercular family history. We may have thought that if a little overweight was good

Total.....	22,112	144,227	1248.1	1187	95.1

for one case of tuberculosis in the family, more was good for two cases.

3. A shows good results, the total mortality being only 86 per cent. The entrants under thirty are very few, for in this symbol both parents attained seventy. As a consequence of the lack of entries under thirty, the mortalities in the weight subdivisions also go against the rule as in X, the lighter weights giving 78 per cent. and the heavier weights 91 per cent. Taking it altogether we must conclude that the long-lived parents have offset the tubercular taint in the brothers and sisters.

4. B and C are too small to give conclusive results, but the two together show a mortality of 100 per cent. only.

5. D shows a mortality of 109 per cent., the lighter weights being a little worse than the heavier weights.

6. In E the mortality is 118 per cent., but the number of deaths is too few to be of any distinct significance.

The definition of Medical Impairment Class 51 is "one parent and a brother or sister dead of tuberculosis or afflicted with it." This class is not large, and naturally contains very few with a long-lived family record, symbols A, B, and C being practically absent. Tables 27, 28, 29, and 30 show the mortality in the whole class and in the symbols X, D, and E, each divided into lighter and heavier weights.

1. The mortality in the class as a whole is high, being 117 per cent. It is high in all age-groups except 50-59. The entrants below age 40 show a mortality of 149 per cent. and those above of 96 per cent.

2. X shows a mortality of 129 per cent., decidedly higher than X in Classes 53 or 55.

3. D shows a mortality of 104 per cent., somewhat higher than D in Classes 53 or 55.

4. E shows a mortality of 148 per cent. A short-lived family history coupled with this amount of tubercular taint seems to be effective in raising the mortality.

5. Besides the deaths in these three symbols, there is a residue of two actual deaths, and between three and four expected death. This represents a mortality of 50 per cent. to 70 per cent. for the long-lived symbols, which is interesting even if the deaths are only two in number.

Total.....	20,598	133,789	951.9	893	93.8

6. In all the symbols the mortality in the lighter weights is greater than in the heavier weights. The following table shows the influence of age on the mortality of the two weight sets:

TABLE I

	Lighter Weights	Heavier Weights
Under 30.....	223%	131%
30–39.....	167%	108%
40–49.....	91%	135%
Over 50.....	57%	93%

This agrees in general with our ideas that the lighter weights suffer more than the heavier weights in the early ages and less in the older ages.

is "two parents dead of tuberculosis or afflicted with it." The results for the whole class and for Symbol E are shown in Tables 31-32 and 50.

1. The number of entrants was very small and nearly all of them belonged in Symbol E.

The mortality for the whole class was comparatively low, 101 per cent. This low mortality, however, disappears if we eliminate the five entrants of sixty years and over. None of them died and they represent a total exposure of fifty years, which at their high ages accounts for 4.1 expected deaths.

If we deduct these from the total expected deaths, we get a mortality of 150 per cent. Probably the truth for this impairment in general would fall about midway between this and the actual result. We will not be far out of the way if we estimate it at 125 per cent.

2. If we apply this method to Symbol E, we get a final mortality of 149 per cent. instead of 134 per cent. as given in the table.

The deaths are too few to permit of further an-

alysis. When we consider that M. I. Class 54 is composed almost entirely of cases with a short-lived family history and that this in itself gives a mortality of 110 per cent. in untainted cases, the tubercular element adds something but not a great deal to the risk. Doubtless the cases were selected with great care and on account of this we should increase the mortality somewhat in order to get a correct result.

Medical Impairment Class 49, whose definition is "both parents and one or more brothers or sisters dead from tuberculosis or afflicted with it," had only sixty-four entrants who gave five actual deaths as against 3.6 per cent. expected deaths, a mortality of 139 per cent. The whole class probably belonged in Symbol E and on this account the cases were doubtless selected with great care. The deaths are too few to justify any definite conclusions or permit any further analysis.

Having reached the end of the tubercular family history groups as defined by the Medico-Actuarial Mortality Investigation, it will be well to summarize our results. The following table shows the mortalities of these seven classes. In the top line for purposes of comparison have been placed the mortalities of the untainted family history. The tubercular family history groups have been arranged in the order of the mortality for the entire class, as actually found, except that the place of Class 54 has been fixed by the estimated mortality as explained when it was discussed. A brief definition of each class has been inserted, the word "Sibling," devised by Karl Pearson, being used to mean either brother or sister. The first column shows the mortality of the entire class and the subsequent columns the mortality of each longevity symbol, so far as it has been determined:

TABLE J

If we look at the first column representing the mortality of each class in its entirety, we will see that the Mutual Life has not suffered by reason of a tubercular family history uncomplicated by other impairments. But we failed to take into account that a short-lived family history is an impairment by itself and when associated with tuberculosis, the combination is distinctly bad, as shown by the mortalities in the column headed E. A long-lived family history is able to neutralize considerable tubercular taint as shown by the mortalities in A, B, and C. These are uniformly good with the exception of 52 C, but this as well as 52 B and 55 A showed too few deaths to be of much significance. Column D shows that an average family longevity secures an average mortality, for its mortality generally agrees with that of the entire class. Column X, representing an indeterminate family longevity,

shows the marked variations expected with such unhomogeneous material.

The presence of tuberculosis in the family history of an applicant always calls for thorough scrutiny and careful selection. In the lesser grades of tubercular taint, this perhaps amounts to nearly as much as was used in securing our untainted family history groups where we eliminated all medical impairments, marked overweights and underweights. In the higher grades of tubercular taint even more care is used and only those risks are accepted who are otherwise excellent. These facts must be borne in mind when we compare these different mortalities with each other, or with the untainted classes. In fact, this extra care in selection affects every deduction which we wish to make in the study of tubercular family history.

We are now in a position to make some general deductions from our studies of tubercular family history.

1. *Age.*—It is evident that a tubercular family history has its maximum effect in the ages prior to 30. Its influence thence diminishes rapidly and after 40 it can be practically disregarded, unless the longevity of the family as a whole is also impaired.

2. *Weight.*—A tubercular family history is neutralized to some degree in the ages below 30 by a weight which is above the average. Between 30 and 40 the effect of this is less pronounced. After 40 the overweight seems to disregard the tubercular element entirely and unless much care is exercised in selection, it will increase the mortality beyond the normal.

3. *Amount of Taint.*—In a general way it may be said that the larger the number of cases of tuberculosis in the family the more apt the mortality is to rise. This general statement, however, is itself influenced by the longevity of the family as a whole.

If that is good, we may expect good results even though the amount of tuberculosis in the family is large. If the longevity is average, we may expect nearly average results, especially if we have used care in regard to weight. If the longevity is poor and the family short-lived, we will get poor or bad results, if there is more than one case of tuberculosis in the family.

4. *Relationship.*—It is natural to suppose that a tubercular parent would have more influence than a tubercular brother or sister in affecting the long-

evity. Table J does not demonstrate this; in fact, it rather leans the other way. Thus 55 is better than 53, and 51 D is better than 52 D. The problem is complicated, however, by the fact that a history of parental tuberculosis undoubtedly called for more care in selection than one of fraternal tuberculosis. After making all allowance for this factor, it is fair to assume that a tubercular brother or sister is as influential in affecting mortality as a tubecular parent.

5. *Heredity and Infection.* These two factors cannot be separated in this study and the effect of environment also is mingled with them. Whether tuberculosis itself is inherited or only a weakness of constitution is a question which has been extensively debated. We are told that 50 per cent. to 90 per cent. of us have tuberculosis at some time in our lives. As only 12 per cent. to 20 per cent. die of it, the vast majority of those infected recover without sensible impairment of health. Nevertheless, the fact that a tubercular family history predisposes to tuberculosis, either by inheritance, infection, or environment, is well shown in Table 33 giving the causes of death.

In the first column have been put the causes of death among all the men insured in the United States and Canada during the same time in the Mutual Life. Classes 49, 50, and 54 have been omitted, for the deaths were too few to justify any conclusions.

The percentage of tuberculosis as a cause of death among all men was 13, but where they have a tubercular family history it ranges from 26 per cent. in Class 55 to 17 per cent. in Class 52.

6. *Kind of Insurance.*—It is well known that endowment policies regularly give a lower mortality than other kinds of insurance. It has been inferred that this would hold true even if there was an impairment present, provided a similar impairment was found in the other kinds of policies. The idea was that the self-selection effected by the applicant when he paid the higher endowment premium was potent even though the endowment was not originally applied for. So far as a tubercular family history is concerned, this idea is a mistake. M. I. Class 51—one parent and a brother or sister dead of tuberculosis—contained 45 per cent. of endowment policies. As our average issues only contain about 20 per cent. it is probable that a good many of these were not originally applied for. Tables 34, 35, and 36 show the experience in them and also the life policies of this same class.

The mortality in the life policies is only 107 per cent., in the limited life policies 101 per cent., and in the endowment policies 144 per cent. While the number of deaths is small, it seems large enough to justify the positive conclusion that the offer of an endowment policy does not of itself improve the mortality due to a tubercular family history, and this is particularly true of the ages below 40.

7. *Family Longevity.*—If the family is long-lived in general, a tubercular taint has but little effect on the mortality. This holds true in all classes where we obtained a family history that was long-lived, no matter how much the amount of tubercular taint.

If the family is of average longevity, a tubercular taint has considerable effect. If the family is short-lived, the mortality is high whether the parental deaths be due to tuberculosis or some other disease.

The importance of family longevity is also shown by Medical Impairment Class 56, the definition of which is "apoplexy or paralysis in the family record, two or more cases." Tables 37, 38, 39, 40, and 41 show the mortality experience of the whole class and of symbols X, A. D. and E.

1. Two or more cases of apoplexy or paralysis in the family seems to be a distinct impairment, as indicated by the mortality of 124 per cent. in the entire class.

2. Symbol X, an indeterminate family history, shows a mortality of 109 per cent.

3. Symbol A, a long-lived family history, shows a mortality of 102 per cent. Although this is reasonably good, it is fifteen points worse than symbol A gives in our untainted family histories.

4. When associated with a short-lived family history, the mortality is 300 per cent. The deaths, however, are so few that no value would be attached to this result if it were not for the fact that it is in accordance with our previous conclusions regarding the influence of family history, though the percentage is exaggerated.

Thinking that weight might have some effect on the mortality the cases were divided into the lighter weights, including build-groups 6, 7, 8, and 9, and the heavier weights, including 0, 1, 2, 3, 4, and 5.

The former showed a mortality of 123 per cent. and the latter one of 125 per cent. These results are practically identical and I hesitate to accept them as conclusive, for we expect to find the combination of apoplexy in the family history and heavy weight to make for a higher mortality.

Heredity, infection, or environment seems to have a decided effect in determining the mode of exit for 21 per cent. of the deaths were due to apoplexy or paralysis, as compared with 8 per cent. among all men. Curiously only two deaths, less than 3 per cent., occurred from tuberculosis.

PROGRESSIVE CURVATURE OF THE RADIUS (MADELUNG'S DEFORMITY) CORRECTED BY OSTEOTOMY.*

BY HENRY LING TAYLOR, M.D.,

NEW YORK.

PROFESSOR OF ORTHOPEDIC SURGERY, POST-GRADUATE MEDICAL SCHOOL; ASSISTANT ORTHOPEDIC SURGEON, HOSPITAL FOR RUPTURED AND CRIPPLED.

IN the year 1878 Madelung, a German surgeon, described very clearly a deformity at the wrist, which he called spontaneous subluxation of the hand forward. Since then this affection has been recognized and described by numerous authors and the subject has been admirably summarized by Stetten, who gives a critical résumé of the literature with 91 references and short histories of the 64

Fig. 1—Case I, 15 months before operation.

cases reported up to 1909. Briefly the literature shows that the deformity comes on slowly, without any clearly assignable cause, at the beginning of puberty or just before. Of the 64 collected cases

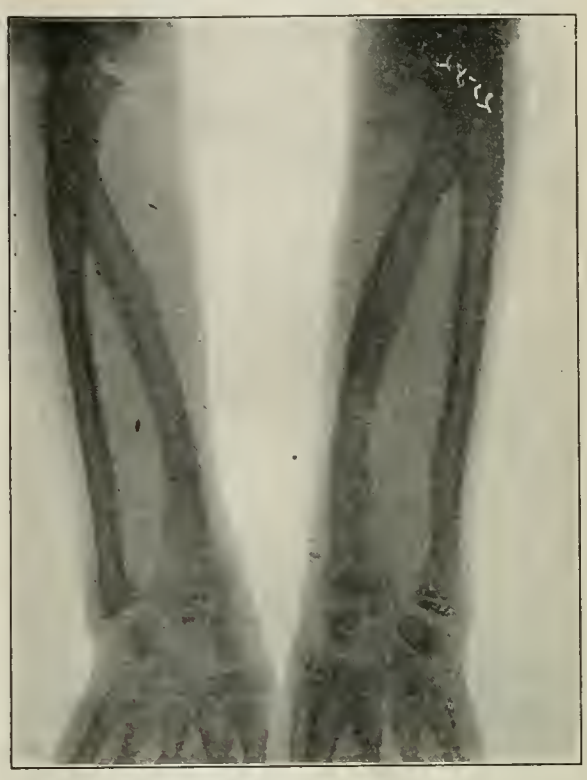

Fig. 2—Case I, October 27, 1910.

55 were females, 8 males, and in one the sex was not stated. In 43 the affection was bilateral, in 20 unilateral, and in one uncertain. The deformity

Fig. 3—Case I, February 3, 1912. Lateral view of right, antero-posterior of left. Before operation.

consisted in 62 cases in a displacement of the hand forward, with marked projection of the ulna backward. Skiagrams show that the radius is bowed with the concavity toward the plantar aspect, car-

*Read at the First District Branch of the Medical Society of the State of New York, Poughkeepsie, N. Y., October 4, 1912.

rying the carpus and hand with it; the ulna, however, does not follow, but becomes separated from the carpus and projects strongly backward. The shaft of the radius is often bowed laterally away

Fig. 4—Case I after operations.

from the shaft of the ulna. The palmar deviation of the radius may be throughout a good part of the shaft or may be confined to the lower end. In two cases reported by Kirmisson and Stetten, the radius deviated dorsally and the wrist deformity was the reverse of the one described.

Local pain, tenderness, weakness, stiffness, and disability are usually associated with this affection, varying in intensity in different individuals and at different stages, but the hands may usually be used in moderation, and under such conditions pain is not a striking feature. The affection runs through its various stages and after a few years becomes quiescent; the deformity and some disability remain.

The causation is still obscure, but it seems to be associated with irregularity of growth at the lower end of the radius, and with the physiological softness and laxity of the tissues at puberty. It is at times a familial affection and abortive forms may also be found in such families. Some writers have considered the affection congenital, which it quite certainly is not, but a congenital dislocation of the lower end of the ulna backward without bowing of the radius has been described by Fosdick Jones. Most of the authors have little to suggest in the way of treatment, but Duplay in 1885 proposed

Fig. 5—Case I after operations.

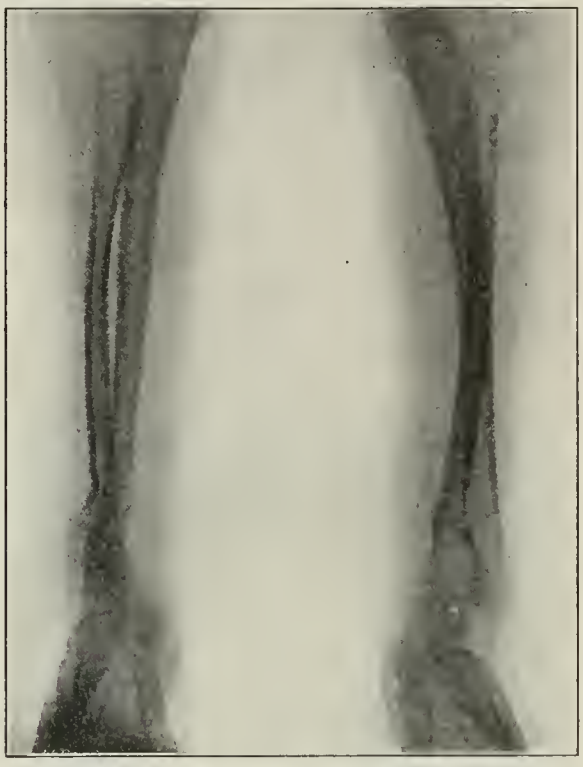
linear osteotomy of the lower end of the radius, and reports two successful results. Delbet also reports a case. Paulson in 1905 proposed oblique osteotomy of the radius, and reports two cases, one successful. He remarks that the operation is hardly applicable to the cases where the bend is low down. Successful cases have been since reported by Putti and Lénormant. In addition Peckham dissected out fibrous tissue below the lower end of the ulna and forced the latter back into position. The literature as tabulated by Stetten, therefore, gives us seven osteotomies, five successful, and Peckham's operation as the operative experience. The references to the affection in the textbooks are few, short and indefinite. The writer has seen several cases besides the two which follow, but unfortunately their notes are not available.

Case I.—*Progressive Curvature of Both Radii—Cuneiform Osteotomy—Cure.*—The first case to be carefully studied by the writer was Helen R., first seen at the Hospital for the Ruptured and Crippled, October, 1910, and then a healthy girl of thirteen.

Fig. 6—Case I, March 11, 1912, right operated upon February 14, 1912. Left not operated upon.

There were four brothers and three sisters, and none of the family had ever had any weakness or deformity of the wrist. She was a school girl and had not done hard work. Our pediatric expert, Dr. Walter Strang, pronounced the patient free from signs of previous rickets. She had had diphtheria at eight and typhoid at nine. At eleven, after using a hatchet she noticed some pain about the right wrist. She has had this pain in both wrists at times since, especially after working, but more in the right. The hands have gradually become dropped and displaced forward, and the ulna very prominent dorsally. For six months or more this deformity has been marked and the wrists have been weak and somewhat stiff. The right wrist can be extended barely to a straight line with the forearm; when this is done the superficial wrist flexors are very tense. The left hand may be extended somewhat further. The right hand is fixed in semipronation, no rotation being possible; on the left

side pronation and supination are limited. The motion at the elbow is free, but the carrying angle is greater than is usual. Radiograms showed the lower end of the radius deviated forward and



Right Left.

Fig. 7—Case I, April 26, 1912. Right operated upon February 14, 1912. Left operated upon March 27, 1912.

turned somewhat toward the ulna; the part of the end of each radius adjacent to the ulna was rarified; the shaft of each radius was also bowed away from the shaft of the ulna. It will be noticed that pain was not a prominent feature, and while stiffness and deformity were pronounced the disability was not extreme; the hands could still be used for many things. It was believed that the deformity at the wrists was due to the sharp deviation of the lower end of the radius and it was decided after more than a year's observation to do a cuneiform osteotomy, base dorsal, at the lower end of the radius, as proposed by Stetten, to correct this. During the interval of study the condition of the patient had not changed appreciably.

Fig. 8—Case II.

February 12, 1912.—The right hand could be passively extended to straight and flexed to 45°; there was no rotation. The left hand could be passively extended to 45° beyond straight, flexed 70°, rotation somewhat limited, active movements several degree less. Pressure above wrist between the ulna and radius was painful; forced flexion was painful on the right side.

Fig. 9—Case II.

February 14, 1912.—A cuneiform osteotomy with a dorsal base of ⅜ inch was done on the right side and the lower fragment with the carpus and hand bent sharply upward at the point of division. The forearm and hand were put up in about 30° of extension. The simple operation was done through a 2-inch incision at the radio-dorsal border of the forearm, 1 inch above the wrist joint. The correction was effected without difficulty and the hand and ulna at once went into place as the distal fragment, with the carpus and hand, was extended. In six days the patient was discharged from the hospital, there having been no reaction, and two days later the plaster splint was split down at the sides, the wound inspected and found to be healed; motion at the wrist was found to be increased.

Fig. 10—Case II, May 8, 1912.

On March 27 the same operation was done on the left radius with the same result.

On May 3, 1912, there was about 35° flexion, about 45° extension, and about one-half the normal amount of rotation. On the left side there was 45° of flexion and also of extension and normal rotation. The patient has done well to date, but she has been advised to apply the palmar splints at night to keep the wrists extended, as there appeared to be a slight tendency to recontraction of the flexors. There was full and free use of the fingers. The patient now is free from deformity, has no pain, and has excellent use of the hands; motion has increased somewhat since the last note.

Case II.—*Bilateral Progressive Curvature of the Radii.*—Elsie B., a healthy girl of fifteen, was seen in May, 1912, at the Hospital for the Ruptured and Crippled. She had been a healthy baby, breast fed, but had an attack of pneumonia in infancy

Fig. 11.—Case II, May 8, 1912.

and at six years; she had also had measles, whooping cough, and mumps in childhood, and bronchitis a year ago. She was pronounced free from signs of previous rickets by Dr. Strang. There were no cases of wrist deformity or weakness in the family. She goes to school and has done no hard work. She noticed the prominence of the ulnæ on the back of the wrists about two years ago, and this has increased since. She had some pain over the ulnar prominences, but not severe or continuous, principally in the right wrist. The trouble has grown worse for the last few months, and the wrists have felt weak. Has apparent displacement of the hands forward, and marked dorsal prominence of the lower ends of the ulnæ. Motion is nearly normal in all directions. She extends both wrists to 60° beyond straight, and flexes to 90°; pronation and supination normal. She has a slight scoliosis to the left, but complains of no other troubles. This patient has only slight pain, and disability, and almost no stiffness. The skiagrams show a forward deviation of the radius at its lower end, caused by a curvature of the lower half of the shaft, which is also curved away from the ulna. There is also some obliquity of the radiocarpal articulation of the epiphyseal line of the radius, and some decreased density at the part nearest the ulna. Osteotomy was advised, but has not been accepted.

These histories give a fair idea of the symptomatology of these cases, and the skiagrams of the pathological anatomy. The first case shows a sharp bend at the lower end of the radius blocking motion; the second shows a more gradual and diffuse curve. There seems to be some disturbance of the area of active ossification adjacent to the distal epiphysis of the radius, where growth is most active, and the deformity seems to be the result of asymmetrical growth. The cause and nature of the process are unknown, but there is nothing to connect it with early rickets, and late rickets has never been more than a doubtful hypothesis. The process may have to do with an exaggeration of the physiological bone softening and tissue laxity of puberty, and may be analogous to adolescent coxa vara, bow leg, knock knee, and flat foot. The affection seems to go through an active stage and then to become quiescent. The accrued deformities and the disabilities determined by these are, so far as we know, permanent, unless corrected by operation. As we have seen, the deformity is easily corrected by a cuneiform or linear osteotomy at the lower end of the radius. Once the characteristics of the deformity are borne in mind the diagnosis is easy, though there are several deformities with which it may be confused, such as those due to an old fracture or dislocation at or near the wrist, and congenital dislocation of the ulna backward without curvature of the radius as described by Fosdick Jones. The history and skiagraphic examination will serve to separate such cases from those of progressive curvature of the radius.

The two cases related in this paper were shown at the Hospital for the Ruptured and Crippled to the members of the American Orthopedic Association May 29, 1912, when Dr. Charles H. Jaeger also showed a girl of 17 with a similar bilateral deformity of the wrists, with radiograms showing radial curvature. The affection is probably not so rare as the small number of cases reported would indicate and as it is easily diagnosed, it is to be hoped that increasing numbers will be recognized and relieved by proper treatment. It is suggested that the affection be known as progressive or spontaneous curvature of the radius.

SOME CLINICAL OBSERVATIONS IN THREE CASES OF HUNTINGTON'S CHOREA.

By MAX A. BAHR, M.D.,

INDIANAPOLIS.

CLINICAL PSYCHIATER, CENTRAL INDIANA HOSPITAL FOR THE INSANE.

Case I.—Female, age forty-six years. Mother, two aunts on mother's side, and one cousin were choreic. Patient had eleven children in thirteen years; four of the children are exceedingly nervous and one of them is described as having "jerky spells." Mother of patient was also insane. Father died of cancer of the omentum. One uncle insane.

Patient had always been in fairly good health until the age of thirty-five years, when she began to have "peculiar twitchings." These movements were first noted in the upper extremities and it was fully two years before they became general as at the present

Fig. 1.—Showing the facial grimacing and contortion, the patient attempting to control the involuntary and incoordinate movements of her arms by clasping the hands.

time. The lower extremities apparently became involved last. The patient's mental change has been noted for about two years. She became aware of her heritage and was consequently rather seclusive with pronounced suicidal tendencies. She also became exceedingly suspicious, vulgar, and profane. Later she developed distinct paranoid ideas, believing that even members of her family were working and plotting against her.

The patient presents on examination involuntary muscular movements of large range and whole groups of muscles are set into action momentarily. This gives the patient the appearance of posturing and grimacing from eccentricity, and when the lower extremities are set in action there is a dancing movement. The queer contortions of the face and head and incoordinate poses of the upper extremities will be noted in Fig. 1. Most of the muscles of the body appear to be simultaneously affected. In the speech there is noted an interrupted articulation which appears to be due to the altered muscular movements of the buccal cavity, pharynx, and respiratory muscles. Disturbance in sensation is negative, with the exception of a slight decrease in the sensibility to pain. The special senses are unaltered. Incoordination is very marked; for instance, when the patient is asked to bring the forefinger to the nose, she attempts to do so in a series of zigzags and fails entirely. It is absolutely impossible for her to walk in a straight line. All movements subside during sleep.

Although the chorea has existed for nine years, the amount of mental impairment is very slight and the paranoid ideas above referred to, as mentioned in commitment record, we believe to have been greatly exaggerated. There is only a very mild degree of dementia. There is considerable depression of spirits but not in the sense of a melancholia. There have been no suicidal inclinations manifested during the woman's stay in the institution. The patient at times becomes very irritable. No hallucinations could be ascertained.

Case II.—Female, age forty-two years. One aunt had chorea which appeared at the age of thirty-four yars. Otherwise no history of the disease could be ascertained. Mother died of some complications following measles. Grandfather was insane. Father was killed while in a state of intoxication. Her mother was considered somewhat "nervous." There was never anything unusual reported as to her birth which would lead one to infer that there could have been anything abnormal.

Patient as a child was always considered rather weakly, although she never had any real illness. Attended school but a few short terms and has had practically but very little education. Can read and write, but otherwise is very ignorant. She worked about in families and on the farm where she was brought up until she was married at the age of twenty-eight. Her husband was a very heavy drinker.

After her first husband's death the patient remarried, but this marriage proved to be a failure, as she states that "this man married me in order to obtain possession of my property." After he learned that he could not do so he left her and she has not heard from him for several years.

No history of alcoholism on the part of the patient. Said that she had always had a lot of friends and had always gotten along nicely with people until her present trouble which had dated back about five years. She said that her entire trouble was merely the result of her son trying to obtain possession of her property. That he had resorted to every means to do so. This son was a drinker and frequently became intoxicated and abused her. Patient had had three miscarriages without apparent cause.

Said that her son became ill last spring and that he had a nurse stay with him during his illness who afterward lived illegitimately with him in his mother's home. "This whole affair was merely to crowd me out in the streets and take possession of my property." "Did they ever try to poison you or in any way get you out of the way?" "Yes, I became very much afraid of this woman, because she has threatened to get me out of the way. Later I refused to eat in my own house, as I feared that there might be poison in the food."

Patient on entering the room appeared rather cheerful and said that she was glad to come over for an examination. No hallucinations could be ascertained at this time. Said that she thought that they might have tried to put poison in her food at

home, but here everybody was her friend and that she had no fear of anything of that nature.

Emotionalism has always been about normal since the patient has been in the institution. At times she becomes "quite blue" to think of the way she had been treated, but she soon forgets about it. No marked dementia could be ascertained. The patient answered all questions within her educational sphere correctly. Of course, as stated above, the patient is very ignorant and questions had to be very limited. She recognized her surroundings and knew everything that was going on about her. No disturbance in the attention, no delusions of any consequence could be ascertained. There was a slight element of ideas of persecution, but there appeared to be considerable basis for her belief as some of the stories she related were true. Patient has been well behaved on the ward and appeared to be well satisfied. Said that she has been better treated here than at any time in her life.

On physical examination the patient presents distinct choreic movements which have been increasing in severity in the past five years. There is sometimes twitching of the entire body. Movements assume a jerky character and appear at times intermittent. Tendon reflexes are increased. Although the finer movements are at times executed with difficulty, the coarser ones are fairly well carried out. Slight tremors of the outstretched hand are particularly observed if the patient becomes slightly excited. A peculiar facial movement produced by a contraction of the frontalis muscle and drawing backward of the angle of the mouth, producing a peculiar grimace, is noticed. These involuntary contractions, which modify the facial expression, cause a hand to start, a finger to move, or bring about a movement of the feet in deviation from an intended direction. The gait becomes progressively erratic and uncertain and resembles that of an intoxicated person, with the addition of gesticulatory movements of the arms and of facial contortions. All these movements subside during sleep.

During conversation the movements appear to be more extensive. Incoordination is very marked, as the patient shows decided swaying when standing with heels together, and especially with eyes closed she is very unsteady. The general muscular strength is unimpaired.

The speech is rather thick, like the speech of an intoxicated person. Many words are very indistinctly articulated. There is noted a characteristic absence of fatigue. Marked tremor is noted in the writing. Pupils regular, equal and react to light and accommodation. Beginning cataract of the left eye. Patient presents a slight asymmetrical development of the face and head.

Case III.—Female, age thirty-five, single, Fig. 2. Four cousins committed suicide. Mother and one sister of patient choreic.

Little could be learned as to the early life of the patient excepting that given by the patient herself. She was a dressmaker and had been working all day and part of the night for some time when the first manifestations of chorea, at the age of thirty-one, were noted. These choreic movements at first were very mild, but gradually became more severe and intense to the extent of the most curious movements of the face and whole body. The ability to walk and use the arms in eating and dressing was retained for a long time, but every action was accompanied by extremely conspicuous associated movements and twitchings of the whole body. When she is in a sitting posture the head is jerked backward and the arms remain in motion, but the lower extremities are comparatively quiet. The speech is thick and hesitating. The sensations are unaffected. The reflexes are very active. Pupils are unaffected.

Apart from the choreic movements, one detects on superficial examination very little disturbance mentally. The patient is somewhat irritable and there is a mild degree of depression. She is very seclusive and remains isolated in her room the entire day. There is some mental deterioration which is especially noted in the form of forgetfulness, superficial range of thought, a partial but not complete loss of orientation, and a loss of early school knowledge. Patient has some slight insight into her condition and is aware of her unfortunate heritage. The four cousins, above mentioned, are supposed

Fig. 2.—Sbowing the effort made by the patient to control the movements, and the characteristic facies with contortion and grimacing. The fingers of the right band assumed an awkward and incoordinate position, being thrown out of focus by the uncontrollable movements.

to have committed suicide because they dreaded the disease, which they appeared to realize was hereditary. The patient has never shown any suicidal tendencies. All movements subside during sleep. Patient at times has become so incoordinate that she falls to the floor.

In conclusion it will be noted that heredity appears to be a constant factor in Huntington's chorea, that all three cases were women, and that the disease developed in all three cases after the thirtieth year of age and before the fortieth year of age. There appears to be a decided tendency toward paranoid ideas.

A defective hereditary endowment is noted in these cases. Two cases presented psychoses in the ancestry aside from the chorea. The occurrence of the disease appears to be kept in families as a dark secret, as is evidenced by many frequent and contradictory statements made by members of the family in regard to its presence.

This subject has a special sociological bearing in the question of marriage of such individuals whose progeny will most assuredly show this morbid inheritance.

I am indebted to Dr. O. Evermann for the accompanying photographs.

TWO CASES OF SEVENTH NERVE PARALYSIS SECONDARY TO ARTIFICIAL CONGESTION.

By B. ROSENBLUTH,

NEW YORK.

The purpose of reporting the two subjoined unique cases is to explain the mechanism of the production of the classical Bell's paralysis. Of all the theories of the pathology of this form of paralysis, that of autopressure of the nerve at its exit, and more rarely in its canal, both of which are bony, has always appealed to the writer and has guided his therapeusis. The occurrence of the palsy from acute congestion goes a long way to prove the thesis.

Case I. A. S., male, aged 55 years, a Russian-Hebrew, tailor by occupation; has been married 35 years, had 9 children, 7 of whom are living. Has been a sufferer with right hemicrania for many years, and is always constipated. This represents all the illness that he ever had in his life.

A few days ago he had a very severe attack of hemicrania, and his physician advised the application of a mustard plaster over the exposed portion of the affected side of the head. The plaster was placed behind and below the ear. Severe congestion and slight vesicat on were soon produced.

The patient noticed that when the burning was at its height he felt "queer" about the mouth, and a little while later he found that he could not close his eye on the right side. Five days later he presented himself at my office with a full-fledged peripheral facial palsy, of the right side of the face, from an affection of the seventh nerve which apparently had not involved it any farther than at the stylomastoid foramen.

The entire right side of the face was immobile, so that the forehead could not be wrinkled, the eye could not be closed, the palpebral fissure was widened, the right side of the mouth drooped and allowed saliva to escape from it at this point; the teeth at the right side of the mouth could not be exposed voluntarily, and on laughing the mouth was drawn to the left by the overaction of the nonpalsied muscles of the left side. There was no sensory disturbance of the ear, face, pharynx, or tongue. The special functions of the ear and of the tongue were normal. There was no subjective or objective vertigo. The eye did not show nystagmus. As very frequently occurs in the catarrhal form of the affection, the stimulating wisp of cotton used for testing touch on the face felt larger on the affected side.

Electrical examination showed diminution of irritability to galvanism and faradism; RD developed a week later. The area over which the plaster had been applied was evident for a long time—over a week after being first seen.

The man remained under treatment for over a year with partial improvement. The palpebral fissure became narrowed, a contracture developed at the nasolabial fold, and there was a slight twitching of the zygomatic group of muscles. For the last two years he has frequently shown himself at my service at the Mt. Sinai Hospital Dispensary (No. 8, series 1910) with the condition last described. The whole period of observation has been over three years. I last saw him at the dispensary in May, 1912.

Case II. N. F. (Beth Israel Hospital Dispensary, No. 649), male, aged 23 years, Russian-Hebrew, 20 years in the United States, single; occupation, student. Has had left hemicrania at varying intervals. Two weeks ago during an attack of pain in his head he applied a mustard plaster over the left mastoid, and below the ear, and went to bed with it. He awoke next morning with a bad mustard burn about the left aural region, and on investigating this in the mirror found that the left eye could not be closed, and the familiar drooping of the mouth with practically all of the subjective and objective symptoms detailed in case No. I were present. Dr. M. R. Walter kindly made an otological examination and reported negative findings from a pathological point of view. Electrically, there was a complete reaction of degeneration, but it reacted to a strong faradic current. The end results were unsatisfactory, although fortunately he did not develop a postparalytic twitch. On account of the early manifestation of such severe symptoms I have no hesitation in aligning this case with the first one, for I know that with the close attention and treatment that were accorded him he would have made a perfect recovery if he had had a catarrhal form of palsy.

The two cases are most uncommon, but instructive withal. There is no difficulty in tracing the neural damage to the induced congestion and hyperemia at a part of its course where the nerve compressed itself against the bony edge of the stylomastoid foramen. The artificial congestion was more severe and of longer duration than occurs in a simple refrigeratory paralysis, hence the greater severity of the neuritis.

Here we can see two facts, that there was a congestion and that there was a paralysis, the latter sequence being such that one cannot but bring forward the former as a factor in its production. Every one has seen induced congestion over the course of superficially placed nerve trunks, as, for example, the ulnaris, or the somewhat more deeply placed branches of the brachial plexus on the inner side of the arm, or even the popliteal, or the very superficial external popliteal (peroneal) nerves. Yet, still, paralysis is the exception, and considering the frequency of irritant application over these parts on account of joint and bone affections, it should be fairly common. These nerves are frequently the seat of neuritis, but seldom of bad palsies from their catarrhal inflammations. But we do see palsy of all these nerves from very slight pressure. So in the case of the facial nerve; it is frequently the seat of catarrhal neuritis due to transitory atmospheric changes in its vicinity, but the transitory congestion lasts long enough to cause the slight amount of autopressure against the bony walls of the Fallopian canal, and the bony edge of the stylomastoid foramen, causing a pressure paralysis.

That a narrow Fallopian canal, or a small stylomastoid foramen will help in its causation cannot be denied, but the infrequency of recurrence of Bell's palsy in the same individual and the rarity of this affection as a familiar disease should place these parts as of secondary or small importance as a

causative factor in the pathology of paralysis. In a very large experience with facial palsy, the last 150 cases of which I have carefully analyzed, there was but one recurrent case and one case occurring in the same family. So, to my mind, the problem of facial neuritis is the same as neuritis of any other nerve in the body.

With this point in view, I have for a few years, even before I had the opportunity of seeing the above described cases, been giving my facial cases ergot, with a view of vasomotor constriction. Of course, the vessels concerned are few and of but small calibre, but it seems to me more rational to use this than the usually prescribed sodium salicylate, which often causes tinnitus, showing congestion of the aural mucosa, in which the lining of the Fallopian canal is also involved (being but prolongations of the same mucous membrane) and thus add to the existing crowding of the already overfilled inelastic bony canal. When ergot is given during the first five days, that is, before there is a reaction of degeneration, one can always be sure that he will positively cure his case. The ergot must be the best, and given in large amounts. It has been the habit of the writer to give a teaspoonful every three hours for a period of five days. Of course, every other adjuvant of neurological practice is fully used.

INDICANURIA AND THE CHLORIDES.

By JOHN C. WARBRICK, M.A., M.D., M.S.,

CHICAGO, ILL.

Do the chlorides bear any relation to the amount of indican present in the urine? Does an increase in the amount of chlorides cause a corresponding increase in the amount of indican? Does the color of the urine bear any relation to the amount of indican present in the urine? In order to find out any definite facts bearing upon this matter a great many specimens of urine were carefully examined from time to time and any points relating thereto were noted. In each instance the amount of chlorides, phosphates, and sulphates were recorded along with the specific gravity and the color, and sometimes the acidity and the total solids. The amount of urine passed in twenty-four hours was sometimes noted as well. During the time the examinations were made no special diet of any kind was followed out at any time, but only the ordinary food was taken at each meal, then after every one an examination of the urine was made and the records were noted for comparison. About twenty-five specimens were singled out from more than two hundred others for certain reasons as having a more direct bearing on the matters in question, such as a high or low specific gravity, a high chloride index, or a high phosphate or sulphate index, while the relation of the amount of indican present in each instance was noted.

In about fifteen cases there were some particular points to notice in the relation of the amount of indican present, especially to the amount of chlorides, which in some of the examinations made was very high and far exceeded the normal daily maximum amount. In nearly every case out of the twenty-five urinary examinations made the chlorides were far beyond the normal daily minimum amount, one instance only being excepted. In every instance but two they ranged far beyond the maximum daily limit also. The presence of uric acid in its various forms was also noted and taken into consideration. The color of the urine in most of the cases was yellowish red and next reddish yellow, thus showing the tendency of urines to be high in color instead of being low. In these examinations the specific gravity of the urine reached as high as 1036, somewhat out of the ordinary, and would tend to give a suspicion of some organic disease being present which, however, was not the case. The two urines having the most indican present, the index at 20 in each case had the chlorides rather high, 28-434 in one instance, and 60-930 in the other. The specific gravity in the former was 1024, and in the latter was 1028. From the report of these twenty-five cases it will be seen just what amount of indican was found in each examination made along with a varying specific gravity and a different amount of chlorides. It will be seen that a good deal of indican may be present in the urine where the chlorides are high along with a high specific gravity at the same time. It will also be noted that with a high specific gravity and a high chloride index only a small amount of indican may be found. Again it may be pointed out that with a high specific gravity of urine, such as 1030, and with the chlorides not very high a good deal of indican may be found. With a low specific gravity, such as 1010, and also with a low chloride index, such as 15-232, under the maximum daily amount a good deal of indican may be present. In many instances no indican will be found, even when the chlorides are high and also when they are low. It would seem that indican is not so likely to be found where the specific gravity is low along with a small amount of chlorides, so it may be stated that the amount of indican present in the urine is in direct proportion to the amount of chlorides found, but as the chlorides seem to be governed mostly by various bodily conditions it may be the amount of indican is in direct relation to such conditions as diet, exercise, disease, the taking of plenty of liquid, etc.

Among some of the points to note in connection with the relation of the specific gravity to the amount of chlorides in the urine and the degree of indican present are the following: (1) A urine yellowish red with specific gravity 1028 and chlorides 35-542 had the indican figure at 10 while sarcinæ were present in it. (2) A urine yellowish red with a specific gravity higher at 1030 and the chlorides increased 40-620 had indican in half the amount of the previous one at 5. This urine contained uric acid in three colors. (3) A urine yellowish red with specific gravity 1026 and chlorides high, 45-697, registered indican at 10 and acidity 10, the chlorides being increased in this to more than the first, but the specific gravity less and indican the same. (4) A urine yellowish red with specific gravity 1026 and chlorides less than any of the preceding had the indican index at 10 and acidity 125. (5) A urine yellowish red with specific gravity 1028, chlorides 30-465, and total solids 84, registered the amount of indican at the small figure of 3. In this case 1300 c.c. of urine were passed in twenty-four hours, and this may account for the small amount of indican present, as the chlorides and specific gravity are fairly high. (6) A urine light yellow with specific gravity very low, 1002, and chlorides low, 10-155, had *no indican*. In this case 1600 c.c. of urine were passed during the day, which may account for the low specific gravity and the fact that no indican was present in the urine.

and the same reason may be given for the chlorides being low. (7) A urine reddish yellow, specific gravity 1018, chlorides 30-465, total solids 71.30, had *no indican*. Seventeen hundred c.c. of urine were passed during the twenty-four hours. In this case the specific gravity and amount of chlorides are greater than in the preceding, more so the latter, but still no indican was found. (8) A urine reddish yellow, specific gravity 1006, chlorides 14-217, and total solids 29.3, had *no indican*. Two thousand one hundred and twelve c.c. of urine were passed during the twenty-four hours, therefore the urine was fairly well diluted, and the chlorides would be lower for that reason. (9) Another urine reddish yellow, specific gravity 1022, and chlorides 35-542, and total solids 102.6, rather high in amount, had *no indican*. Uric acid was present in the urine and sarcanæ were plentiful Two thousand c.c. of urine were passed during the twenty-four hours. (10) A urine reddish yellow, specific gravity 1012, chlorides 22-340, total solids 58.7, had *no indican*. In this case 2112 c.c. of urine were passed in twenty-four hours. (11) A urine yellowish red, specific gravity 1026, chlorides 40-620, acidity 25, had the indican index at 20. In this instance the chlorides are high and the amount of indican is more than in any of the foregoing cases. Stomach disorder was present in this case. (12) A urine yellowish red, with the high specific gravity of 1034 and the chlorides also high, 40-620, had the indican index at much less than the preceding, the figure being 5, whereas it would be expected to be higher. A stomach disorder was noted here also. (13) A urine yellowish red, specific gravity 1028, and chlorides 60-930, had the indican index at 20. (14) A urine yellowish red, specific gravity 1028, and chlorides 35-542, had the indican figure at 10. (15) The last urine yellowish red, specific gravity 1030, and chlorides 20-310, had the indican figure at 15. There is more indican present here than in Case 2, which has the same color and specific gravity and twice the amount of chlorides, while there is almost as much indican as in Case 13, where the chlorides are three times as great.

URINES.

Antagonism of Anthrax and Pyocyaneus Bacilli.—H. L. Boidin refers to the recent experiments performed by M. Fortineau of Nantes, who showed that such antagonism exists, and that it may be utilized in the treatment of anthrax in human beings.—*La Presse Médicale.*

THE TREATMENT OF INTERSTITIAL KERATITIS BY SALVARSAN.

By GEORGE W. VANDEGRIFT, M.A., M.D.,

NEW YORK.

INSTRUCTOR IN OPHTHALMOLOGY CORNELL MEDICAL COLLEGE, ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY.

Before reporting the results of treatment of interstitial keratitis by salvarsan it is well to sum up our experience in its treatment by mercury. Two points in particular are worth emphasis; first, that the acute stage of interstitial keratitis under the ordinary mercurial treatment persists for six to twelve months, frequently longer; second, that the amount of connective tissue remaining in the cornea after the cessation of the acute inflammation depends on the duration and intensity of that inflammation. The briefer the inflammation the less connective tissue will be deposited and the better therefore the ultimate vision. If the inflammation has been mild and confined to the edge of the cornea the scar tissue will be slight. If the inflammation began in the center of the cornea (a type much more serious than the former) then the infiltration will be denser, more slowly absorbed, and the vision at the end will be impaired seriously.

The following cases were treated locally with atropine and hot bathing. No other general medication was given besides salvarsan, which was administered in an oily vehicle intramuscularly.

Case I.—E. W., age 15. In June, 1911, this boy came to me after having had mercurial inunctions for six months, since the beginning of the interstitial keratitis. Each cornea was a mass of exudation, over the lower half of which was a salmon patch. No corneal tissue was distinguishable. In the center of each mass was what appeared to be a perforation, but which later proved to be a hernia of Descemet's membrane through a central necrosis of the cornea. The conjunctiva of each eye was intensely inflamed and the upper ocular part was necrotic, perforated, and excreting pus. Vision was reduced to the perception of intense illumination only. The face presented the physiognomy of inherited syphilis with Hutchinson's teeth. The Wassermann reaction was + + +. The patient entered the hospital and received salvarsan full amount of ampule. The conjunctival abscesses subsided under local treatment, and two weeks after the first injection of salvarsan a second full one was given. Within a few days after the second injection the corneal infiltration began to be absorbed till at the end of four weeks from the second injection every trace of acute inflammation had passed away, and the patient read 20/70. Since then the infiltration in the center of the cornea has been clearing till at the present time the vision is 20/40. November 15 the Wassermann being positive a third full injection of salvarsan was given.

Case II.—N. C., age 13. October 15, 1911, this girl came to me presenting the usual symptoms of interstitial keratitis of the right eye, duration four weeks. The lower half of the cornea was covered by a salmon patch. Vision was reduced to counting fingers at three feet. She had the physiognomy of inherited syphilis and the Wassermann was + + +. An immediate injection of a full dose of salvarsan was given. Within a week the process was checked and improvement began. After two weeks from the first injection another full injection of salvarsan was given, at which time every trace of acute inflammation had disappeared. At the end of one

month from the first injection the vision was normal, a few thin scars remaining in the corneal tissue. A third full injection of salvarsan was given December 15, the Wassermann being faintly positive.

Case III.—A. C., age 20. This girl was first seen by me August 1, 1911. She had had interstitial keratitis of central type in both eyes for four months. Vision, light perception. Physiognomy of inherited syphilis suspicious; Wassermann +++. Full injection of salvarsan given August 10. Second injection given September 15, up to which time no improvement was noticeable. After the second injection improvement began and progressed slowly till the middle of November, when the vision became 20/70 and all acute inflammation had disappeared. On January 9, the Wassermann being faintly positive, a third full injection of salvarsan was administered.

In none of these three cases up to the present day (September 1, 1912) has there been a relapse, and the Wassermann still is negative.

Nothing in our experience in the treatment of interstitial keratitis has approached the efficacy of salvarsan. No doubt these cases could have been cured with mercury, but in a very much longer time, during which connective tissue would have continued to be deposited in the cornea, and the ultimate vision would have been much worse. The salvarsan has worked so quickly, and this is particularly so in my second case that was incipient, that little connective tissue had time to form. In each case, also, the corneal infiltrate even after subsidence of the all inflammatory signs has been absorbed to a much greater degree than could be hoped for with mercury. We do not expect to absorb the old scars of a past interstitial keratitis with salvarsan or by any other treatment, but if salvarsan is used when the least trace of acute symptoms is present it will not only check the inflammation but will absorb the infiltrate and prevent further deposit of connective tissue.

147 East 18th St.

Relation of Spleen to Blood Destruction and Regeneration and to Hemolytic Jaundice.—R. M. Pearce, J. H. Austin, and E. B. Krumbhaar conclude that the rapid injection of more than 0.06 of a gram per kilo of hemoglobin intravenously into a normal animal is followed by the appearance of hemoglobin in the urine (pelvis of kidney) within eight to ten minutes. After the rapid injection of more than 0.012 of a gram per kilo per minute of hemoglobin, 16 to 36 per cent. of the total amount, if this equals 0.25 of a gram per kilo, is eliminated in the urine and is accompanied by choluria. If the injection of not more than 0.35 of a gram per kilo is made slowly (less than 0.01 of a gram per kilo per minute), the amount eliminated in the urine is only 2.33 to 9.5 per cent. of the total amount injected, and choluria does not occur. The concentration of free hemoglobin in the blood which constitutes the threshold value of the kidneys for hemoglobin is approximately 0.06 of a gram of hemoglobin per kilo of body weight. When about this concentration is reached, hemoglobin appears in the urine. The amount of hemoglobin per kilo of body weight which, after rapid injection, may be retained without jaundice, is approximately 0.18 of a gram. When 0.22 or 0.23 of a gram is retained bile pigments appear in the urine. The threshold of the liver for jaundice in point of hemoglobin saturation lies, therefore, between 0.18 and 0.22 of a gram per kilo of body weight. With slow injections a greater amount may be retained without choluria. The absence of the spleen does not alter greatly the percentage of hemoglobin eliminated by the kidney, nor does it raise the threshold of the liver for jaundice. In the presence of jaundice, either hemolytic or obstructive, the amount of hemoglobin retained by splenectomized animals is slightly diminished and that eliminated by the kidneys is correspondingly increased.—*Journal of Experimental Medicine.*

Medicolegal Notes.

X-Ray Burn—Holding Hand Too Close to Machine.—Action was brought for damages against a surgeon for an *x*-ray burn alleged to have been caused by the negligent, careless, and unskillful application of *x*-rays to the palm of the plaintiff's hand. The plaintiff's petition alleged that the defendant negligently caused the palm to be exposed to the rays eight or nine times, and for such lengths of times as to cause the skin, muscles, etc., of the hand to be burned, whereby the hand became badly swollen, poisoned, and diseased. This complaint, it was held, did not limit the allegation of negligence either to the use of the rays at all, or to the number or length of the exposures, but included negligence generally in the application of the rays, so that the plaintiff was entitled to recover on proof of negligence in directing him to hold his hand too close to the machine, notwithstanding the uncontradicted evidence that the kind of treatment and times of application were proper.

The court charged the jury that one who holds himself out as a physician and surgeon must use reasonable skill and diligence in the treatment of those employing him and if the defendant undertook to treat the plaintiffs' hand for eczema by the *x*-rays and exposed it thereto eight or nine times for such lengths of time as to severely burn the hand, they should find for the plaintiff. It was held that this instruction was misleading, because too indefinite and uncertain. It should have required the jury to find the specific act of negligence shown by the proof, *i.e.* the placing of the hand too close to the tube of the machine. The defendant informed the plaintiff that there was always danger connected with the treatment, and the plaintiff agreed to assume the risk. The defendant was entitled to the benefit of that express agreement. But the assumption was limited to risks attending the use of the *x*-rays in a careful and skillful manner; it being contrary to public policy to allow the doctrine of assumed risk to include an injury caused by the physician's negligence in exposing the plaintiff's hand so close to the machine as to burn it seriously. Judgment for the plaintiff was reversed and the case remanded for a new trial.—Hales v. Rainis, (Mo.) 141 S. W., 917.

Insurance—What Constitutes a Consultation.—A question in an insurance application asked whether the applicant had been treated by or had consulted any physician in regard to personal ailment within the last seven years. The answer was in the negative. In an action on the policy the evidence showed that the insured had on a specified date told a physician he had a headache, for which the physician gave him headache tablets. The doctor made no examination of the insured and asked him no questions about the headache complained of. It was held that this was not a consultation or a treatment within the meaning of the question. It was also held that the question, when considered in connection with another question as to whether the applicant had ever had any local disease, personal injury, or "serious illness," referred only to ailments of a substantial nature, and not to a mere temporary functional indisposition.—Modern Woodmen of America v. Miles, Indiana Supreme Court, 97 N. E. 1009.

Evidence as to General Health.—In an action upon an accident assurance policy a physician who saw the deceased socially very frequently was allowed to testify as to his general health, although he rarely attended him professionally.—Standard Accident & L. I. Co. v. Wood, Maryland Court of Appeals, 82 Atl. 702.

Insurance-Physician's Certificate as Evidence.—In an action on an insurance policy the defense was breach of warranty stipulating that the insured had not consulted a physician within five years. It was held that the breach of warranty was not established by the certificate of a physician, attached to an application by the insured to the board of education for leave of absence with pay, reciting that insured was suffering from influenza and tonsillitis, in the absence of any evidence that the insured consulted the physician for the purpose of treatment.—Smith v. Travelers' Ins. Co., 135 N. Y. Supp. 18.

Intoxicating Liquor Act.—The Kentucky statute provides that any person who shall "sell, barter or loan" any intoxicating liquors in a local option district shall be punished. A physician gave whiskey to a person who said he wanted it for a child who had the measles. There was no agreement that it should be returned and the physician did not request its return. It was held that the physician was not guilty of violating the act merely because the person returned the whisky.—Commonwealth v. Abbott, Kentucky Court of Appeals, 145 S. W. 373.

MEDICINE AND THE DRAMA.

IF the purpose of the drama is "to hold the mirror up to nature," surely the work of the dramatist is the most difficult of the fine arts. He who is content to portray the lighter and superficial phases of human conduct is less likely to violate the above fundamental canon than he who would seek to uncover the innermost sources of human action. There is a growing tendency in the modern drama to interpret for the popular mind the abstruse problems of psychology. It plunges boldly into the depths of the occult, and does not hesitate even to grapple with some of the unsettled problems of medical science. The productions of the modern stage, apart from those that appeal merely to the senses, handle without reserve the moot points of heredity and subconscious cerebration, and even endow with real life and blood the shadowy images of the spirit world.

The interest of the physician in the drama is threefold: as the spectator, as the one who sees himself portrayed or parodied on the stage, and as the critic. In the first of these rôles the medical man easily secures a needed relaxation from his daily cares. As a character in the play itself, the type of the physician has been from the very beginning of the drama until the present time one almost exclusively of buffoonery or of villainy. The *Médecin malgré lui* of Molière finds its modern counterpart in the scheming charlatan of the stage. The dramatic art has not yet outgrown the ancient conception of the inferior social position of the medical man. The noble traits of the latter's nature do not appeal to the dramatist looking for sharp contrasts. The average playgoer may cherish a secret satisfaction in witnessing the caricature of the type of man at whom he is wont to cast his careless gibe, but to whom he inevitably bows in his distress. With the increasing modern conception of the sacredness of the physician's calling, however, there is gradually passing away the traditional comical representation of the doctor on the stage. The most important phase of the physician's relation to the drama is that of critic. He who is brought so closely into contact with life in its myriad aspects, may fairly be justified in setting himself up as a critic of the drama. He will, perhaps, not essay to deal with its literary or mechanical merits. But the subject-matter of the play, the unfolding of the plot, the portrayal of character, and the estimation of human conduct, are all properly within the jurisdiction of the physician's analysis and comment. This authority of critic is all the more to be recognized when the dramatist handles such biological problems as heredity or enters the realm of psychiatry.

Conspicuous in the modern drama and, in fact, in the drama of all ages and countries, is the predominance of the sex element. A perennial interest attaches to this, the most powerful instinct of the race. Unfortunately the art of the playwright is not always confined to the sublimated and esthetic phases of this mainspring of human emotion, and only too frequently the drama responds to the demands of a prurient patronage. The sensuous beauty of its music, the charm of its color, and the power of its acting could not transfigure the sadistic motif of Strauss's operatic masterpiece. The polygamous element in human nature finds its dramatic representation in countless variations and suggestions on the modern stage. The average playhouse does not by any means provide a salubrious moral atmosphere for the young nor does it assist in refining the grosser instincts of the adult.

In his search for novelty the dramatist invades the cloister and the confessional, the consulting room and the laboratory. Armed with the results of cursory reading and superficial study, he handles the mysteries of faith and of life with the calm satisfaction of an expert. The picture presented to the public is usually one either of unreality or of travesty. Old-time prejudices and discarded doctrines are actually paraded upon the stage as established truths. Thus, the belief in maternal impressions forms the keynote of one of the newer plays presented in New York. The heroine, a victim of double personality, is supposed to inherit the kindly disposition of her father (who, by the way, is a physician) and the malignant traits of the hypnotist who wrought his evil spell over the mother while the child was still *in utero*. Admitting the reality of a double personality, one perceives, nevertheless, that the author ignores the present scepticism of the medical profession with reference to maternal impressions and utterly disregards the Mendelian theory of heredity. This play is but one of many in which there is clearly seen the hand of the amateur dabbling in scientific subjects. The drama is a powerful agency in teaching and in elevating the taste of the public. At the same time it may be a potent instrument in disseminating falsehood and in degrading the finer instincts of humanity.

Another phase of this subject is the growing tendency to read new meanings into some of the older masterpieces of the stage. Shakespeare never dreamed of the thousand and one interpretations which his generous German and English commentators have placed upon the prolific fruits of his genius. Little did he know that in creating the immortal characterizations of Macbeth, Hamlet, and Othello he set up, according to the Italian criminologist Enrico Ferri, perfect types of the born criminal, the criminal lunatic, and the emotional criminal. If the bard of Avon could read some of

the literature of the Freudian school, he would probably be shocked to learn that Hamlet's vagaries were the result of an erotic attitude toward his own mother.

The drama is at once an index of civilization and a potential factor in its advancement. The physician, to whom more than to any other man is accorded the opportunity of reading the heart of humanity, may rightly claim the prerogative of an enthusiastic patron and a qualified censor of the stage. At any rate he should not remain mute when falsehood or error dons the buskin and wears the mask.

DISEASES OF OCCUPATION IN THE UNITED STATES.

With the flocking of the population to cities, and the increase of manufacturing in this country, industrial diseases become more evident. In the large cities, and in New York in particular, there are immense numbers of people who work in factories and at home in many instances under conditions the reverse of sanitary. At the recent International Congress on Hygiene and Demography held in Washington many valuable papers were read dealing with this matter. According to H. Linenthal of Boston, in spite of the influence of industrial processes and of labor conditions upon the health of the community our knowledge and statistical data are meager, due largely to the following causes: (1) With few exceptions occupational diseases are not under the law reportable to the health authorities; (2) physicians are not sufficiently familiar with industrial processes or even with the processes designated as dangerous, so that they fail to recognize the relation of morbidity to occupation; (3) statements of occupation on morbidity and mortality records are too general or inaccurate to be of any great value; (4) inspection of industrial establishments is as a rule carried on by men entirely unfamiliar with health matters; (5) there is a lack of realization among both employers and employees of the dangers involved in certain processes. Linenthal thinks that, in order to protect the workers from the ill effects upon their health of industrial processes or insanitary conditions the following measures should be adopted: (1) To collect complete and accurate data regarding industrial processes and the conditions under which the various industries are carried on; (2) to insert more accurate and detailed information relative to occupation on morbidity and mortality records; (3) to instruct the medical student in this important field of preventive medicine by a course of lectures on the more important industrial processes and the diseases to which they give rise; (4) to place the specific industrial diseases on the list of diseases notifiable to the central health authority; (5) to examine periodically all workers in certain industries, these industries to be named by the central health authority; (6) to exclude minors and women from certain industries which are designated by the central health authority as injurious to health; (7) to have adequate laws regulating sanitary conditions and protective devices in industrial establishments and to have such laws intelligently enforced; (8) to have the central health authority issue regulations for certain dangerous trades with instructions to employers and employees how to guard themselves against the ill effects of their work, and to have such instructions posted in the workrooms; (9) to carry on an extensive educational campaign among both employers and employees as to the value of protective measures and good sanitary conditions.

As a matter of fact Massachusetts is the only State which has good laws fairly well enforced in regard to industrial labor. As readers of other papers at the Congress pointed out, throughout the United States there is a lack of health legislation relating to industry. If Linenthal's propositions could be carried into effect in all parts of the country, the result would be beneficial not only to the worker but to the whole community. Without legislation little can be done, for the large majority of employers will not spend money to ensure good sanitary conditions in their factories or workshops unless compelled to do so by law. They should be so compelled and that quickly.

Another phase of the industrial problem which commands attention is the relation of factory labor to infant mortality. Two papers were read at the recent Congress on this subject and these seemed to conflict. The first by Mr. Charles H. Verrill dealt with infant mortality and its relation to the employment of mothers in Fall River, Mass., and his conclusions were that the employment of mothers had but slight influence upon infant mortality. In the second paper Dr. George Reid of Staffordshire, England, stated that by his investigations with regard to infant mortality in relation to factory labor he had convinced himself that the employment of mothers in factories had a decidedly adverse influence on infant mortality. It would appear that such would naturally be the case, for the infants of mothers going out to work would be chiefly nourished on artificial food. It is acknowledged that breast feeding checks infant mortality largely, and therefore factory working by mothers, rendering necessary the use of artificial food for infants, must increase infant mortality. One important lesson to be learned from the papers read at the International Congress on Hygiene and Demography with respect to diseases of occupation is that legislation is needed in all parts of the United States to safeguard the health of those engaged in industrial work.

Latent Eclampsia.

The expression "eclampsia without convulsions" is justly repudiated, since it is practically equivalent to "convulsions without convulsions." There is of course a well-defined condition which goes by this name and for the designation of which the term latent or masked eclampsia may be justifiable as a metaphor, but which should be entitled to a more positive appellative. In recent years latent eclampsia has come to be recognized as a particular clinical form of gestation toxicosis. It is by no means clear that conditions so described are always one and the same thing. It is conceivable that the

toxemia may be so profound that the convulsive phase is skipped, the patient passing at once into fatal coma. Eclampsia is that form of toxemia of pregnancy which develops at or near the time of labor or in the puerperium. In a large percentage of cases it is the convulsions, or the special factors which bring them about—such as high blood pressure, which constitute the real disease and are the actual cause of death. Yet when no convulsions occur it is claimed that this is due to the very intensity of the toxemia. There is evidently a paradox here, when too many convulsions produce the same results as no convulsions at all. Articles in the *Berliner klinische Wochenschrift,* September 9, by Gottschalk and Freund show that "eclampsia without convulsions" is essentially a post-mortem diagnosis. The authors find subjects with all the autopsy signs of eclampsia yet with no history of the latter. There are parenchymatous degenerations in the liver and kidneys, acute hemorrhagic diathesis, and perhaps dubious finds in the placenta. Until the obscurity attendant upon these cases can be effectually cleared up, the diagnosis of "latent eclampsia" may perhaps, as already stated, be justifiable.

Scleroderma and "Idiopathic" Atrophy of the Skin.

The affection once believed to be a primary atrophy of the skin, and later recognized as having, in some cases at least, a definite initial inflammatory stage, evidently stands in a more or less close relationship with scleroderma. Either may appear in a local or diffuse form, and each may show a preliminary active phase which is the precursor of the trophic changes. Moreover each form may attack the extremities causing special clinical types. The near relationship of these two affections is perhaps exemplified further in a case reported to the Leipzig Medical Society last summer by Riecke (*Münchener medizinische Wochenschrift, September* 24) in which the two were said to exist side by side. The patient, a woman past middle life and of neurotic tendencies, developed after cold bathing a diffuse condition diagnosticated readily as scleroderma. Some of the lesions encountered in the examination were, however, of much greater age, and had never shown any of the peculiar manifestations of scleroderma. The localization of the two affections was distinct, the simple atrophy being limited to the backs of the hands and one thigh, while the sclerodermatous patches occupied chiefly the legs and feet, the back, and the upper region of the chest. Riecke had already seen one case of this association, and will report the subject in full. Thus far he has expressed no opinion as to its rationale. The most plausible supposition lies in the existence of a structural predisposition, in virtue of which indifferent causal factors may set up involutional processes.

The Use of Salvarsan in Tuberculosis and Anemia.

The thought that possibly the good results produced in severe cases of syphilis by means of salvarsan might possibly be due to the effect of the drug upon the body apart from its parasitotropic influence, led Maurice and André Bernay of Lyons to try the effect of salvarsan in cases of tuberculosis and of anemia. Atoxyl had already been employed in the treatment of the former disease by Knotte of Odessa, and Herxheimer and Altmann had obtained apparently favorable results in the treatment of lupus vulgaris by means of salvarsan. The Bernays report their own experiences in the *Journal de Paris,* August 24, 1912. There was some experimental basis for this form of chemotherapy, for J. Nicolas, P. Courmont, and M. Gaté announced before the Société de Biologie, July 27, 1912, that by means of injections of salvarsan in the rabbit and goat they had succeeded in causing a considerable increase of agglutinins with reference to the tubercle bacillus. As regards the clinical results of the intravenous injections of salvarsan in cases of tuberculosis the authors note that these injections are followed by a gain in weight, strength, and appetite, and an increase in the number of red blood cells. Pulmonary lesions show a striking improvement, which is, however, most marked in the case of the tracheobronchial glandular enlargements. The program of treatment carried out is an elaborate one. In addition to a séance of thermotherapy and of inhalations of ozone, the patients receive daily hypodermic injections of a solution of methylarsinate or of cacodylate of sodium, and every six to eight days an intravenous injection of 0.10 to 0.50 gram of salvarsan. A contraindication to this method is the presence of hemoptysis. Results as striking as those which were obtained in tuberculosis were observed by the authors in cases of anemia in which the intensive arsenical therapy above described was applied. Lately they have substituted neosalvarsan for salvarsan.

News of the Week.

Surgical Congress.—The third annual session of the Clinical Congress of Surgeons of North America will be held in New York City on November 11 to 16, 1912, under the presidency of Dr. Albert J. Ochsner, who has had the assistance of a large number of eminent surgeons in the preparation of a most valuable program. In practically every large hospital of New York and Brooklyn surgical clinics will be held both morning and afternoon throughout the week, while at the evening sessions in the grand ballroom of the Waldorf-Astoria a number of papers on a variety of surgical subjects will be presented and discussed. The headquarters of the Congress will be at the Waldorf-Astoria, and here each day a complete bulletin of the clinics and demonstrations to be held on the succeeding day will be posted. Invitations to the Congress may be obtained upon application to the secretary, Dr. Franklin H. Martin of Chicago, and membership cards admitting the bearer to the clinics and scientific sessions will be issued at the time of registration upon payment of a fee of five dollars.

For Defective Children.—The Department of Public Charities of New York City announces that it will soon open a bureau for the examination and classification of defective children, which is described as a clearing-house. To it children may be referred by the Departments of Education, Health, Immigration, and Public Charities, and by children's courts, societies for the safeguarding of children, dispensaries, etc. The bureau, which will be under the charge of Dr. Max G. Schlapp, will make a careful examination of each child referred to it, to determine the nature of its feebleminded-

ness, and whether it is or is not likely to be dangerous to the community by reason of criminal tendencies, and will decide upon the proper course of action in each case. For the present such examinations will be conducted by Dr. Schlapp at the Post-Graduate Hospital, but later the Department will submit plans for a site and building for the purpose to the Board of Estimate.

Public Cups on Trains.—Surgeon General Blue has urged upon Secretary MacVeagh the desirability of issuing an order banishing public drinking cups on all railroad trains. Many of the States have already passed laws prohibiting the use of such cups, but these, of course, are operative only within the State, and the Surgeon General believes that it is time for the Government to insist upon the adaptation of the reform by Interstate roads.

Charitable Gifts.—The Day and Night Camp for Tuberculosis in St. Louis, which is to be ready for opening by Thanksgiving time, has recently received a gift of $10,000 from Miss Helen Gould.

By the will of the late Mrs. Brockholst Cutting of Newport, R. I., the corporation of the St. Clare Home of Newport receives the sum of $50,000 to build or equip a building to be known as the Cutting Memorial and to be used by the White Sisters for the care of the sick poor. For the maintenance of this memorial the sum of $100,000 additional is left in trust.

The Adirondack Cottage Sanitarium of Saranac Lake, N. Y., receives a bequest of $25,000 under the will of the late Mr. William Hall Penfold of New York, who died recently. In addition, St. Mary's Free Hospital for Children and the Presbyterian Hospital of New York receive $10,000 each, and on the death of the residuary legatee the sum of $300,000 is to be divided among a dozen charitable institutions, among which are the Presbyterian Hospital, St. Luke's Hospital, the Manhattan Eye, Ear, and Throat Hospital, and the Home for Incurables, New York, and the Adirondack Cottage Sanitarium.

By the will of the late Mr. Sebastian D. Lawrence, the city of New London, Conn., receives a gift of $198,000 for the erection of a hospital to be known as the Joseph Lawrence Free Hospital, and a trust fund of $200,000 for its support, the request being made that no nurses under the age of thirty be employed in the institution.

Armor against X-Rays.—A discovery which will, it is hoped, remove the risks of *x*-ray operators, was announced recently at a meeting of the French Academy of Sciences by M. Droit, who had been impressed during some experiments with the remarkable capacity of silk to absorb metallic substances. With the aid of silk manufacturers, M. Droit succeeded in preparing a silk so impregnated with lead and other substances as to be impenetrable to the rays. One piece of silk thus charged weighs 266 grams to the square meter, and a glove made from it has proved a complete protection against the rays.

Decision against Dr. Kunitzer.—The Appellate Division of the Supreme Court of New York handed down a decision on October 18, denying the appeal of Dr. Robert Kunitzer from the ruling of the Supreme Court which in turn had refused to grant him an injunction against the New York County Medical Society. As has previously been stated, Dr. Kunitzer has charged that his expulsion from the Society was the result of an unfair trial, that the proceedings were irregular, and that the votes were improperly counted. The decision of the Appellate Division was rendered without an opinion and was unanimous.

Is the Cow Passée?—From Germany comes the announcement of the production of synthetic milk, more nourishing and more easily assimilated than cow's milk, quite as palatable, and of the same color. The method of manufacture is secret, but it is said to be composed entirely of vegetable ingredients digested by machinery instead of by the cow. In London the building of a factory for the preparation and sale of the product has been proposed.

Collective Investigation of Ulcer of the Stomach.—At the invitation of the German Committee organized for "A Collective Investigation of Ulcer of the Stomach," a similar committee has been formed in this country, consisting of Drs. George Brewer, Warren Coleman, Max Einhorn, James Ewing, J. M. T. Finney, Arpad G. Gerster, John C. Hemmeter, Frederic Kammerer, J. Kaufmann, William J. Mayo, Willy Meyer, Wm. Gerry Morgan, John B. Murphy, Franz Pfaff, Maurice H. Richardson, William L. Rodman, Charles G. Stockton, and John S. Thacher. The purpose of the investigation is to collect data enabling clinicians to clear up the various moot points in the etiology of ulcer of the stomach, thus facilitating its recognition and treatment. For this purpose surgeons are requested to send the material obtained from ulcer cases at operation (resected ulcers, pieces of mucous membrane), properly preserved, to a central bureau for examination. Of equal importance would it be if pathologists would also send material of gastric ulcers and scar tissue from the post-mortem table to the same central bureau, at the same time filling out the autopsy blank. Finally it would be desirable that all clinicians, internists as well as surgeons, should fill out the history blank, but only in cases which come to operation or autopsy. The central bureau of the American Committee is the Pathological Department of Cornell University Medical College, 477 First Avenue, New York City, where Prof. Ewing will make the pathological and bacteriological examinations of the anatomical material, the results of which will be published by him. The American Committee seeks the cooperation of all physicians, surgeons, and pathologists who may be willing to assist in the investigation. Due credit will be given in the published analysis of the cases to all who send histories and anatomical specimens. Directions for preserving and forwarding the anatomical specimens are given upon the history and autopsy blanks. The autopsy reports should be sent with the specimens to Prof. Ewing. The clinical histories may be forwarded with the specimens, or may be sent direct to the Secretary, Dr. Warren Coleman, 58 West 55th Street, New York City.

Registration Rescinded.—At a recent meeting, the Board of Regents of New York State rescinded the registration of the following institutions: Oakland College of Medicine and Surgery, Oakland, Cal.; Medical Department, Howard University, Washington, D. C.; Chicago College of Medicine and Surgery, Chicago, Ill.; Valparaiso University Medical Department, Valparaiso, Ind.; Hahnemann Medical College of Chicago; College of Physicians and Surgeons, Chicago; College of Homeopathic Medicine, State University of Iowa;

College of Medicine, State University of Iowa; Kansas Medical College, Department of Washburn College, Topeka, Kan.; College of Physicians and Surgeons, Baltimore; School of Medicine, Boston University; Medical Department, Creighton University, Omaha; Dartmouth Medical School, Hanover, N. H.; Cleveland-Pulte Medical College Cleveland, O.; College of Medicine, University of Tennessee, Memphis, Tenn.; Medical Department, Vanderbilt University, Nashville, Tenn.; Milwaukee Medical College, Department of Marquette University, Milwaukee, Wis.; Wisconsin College of Physicians and Surgeons, Carroll College, Milwaukee, Wis.; Manitoba Medical College, Winnipeg; Faculty of Medicine, Dalhousie University, Halifax, N. S.; Faculty of Medicine, University of Toronto, Canada; Faculty of Medicine, McGill University, Montreal, Quebec.

Does Not Want Consumptives.—The Anti-Tuberculosis Association of Texas has recently issued statements setting forth the reasons why it is disadvantageous for sufferers from tuberculosis to go to Texas in hope of relief. The climate is suitable, it is said, but there are very few hospital facilities and no opportunities for work for invalids. The influx of consumptives into the State has been large within recent years, and the Texans are desirous of restricting it.

The Cornell University Medical College opened on October 2, 1912, with an enrollment as follows: For the degree of M.D., first year, 39; second year, 24; third year, 20; fourth year, 19; special students (work not leading to the degree of M.D.), 5; Doctors of Medicine engaged in research, 7; for the degree of Ph.D., 2; making a total of 116 students. There is an increase over last year of 15 students in the enrollment for the course leading to the degree of M.D. All students now registered, with the exception of those who are pursuing the combined seven year courses leading to the degrees of A.B. and M.D. are graduates in Arts or Science, or Doctors of Medicine doing advanced work.

Rat Census.—The first rat census of the United States is about to be undertaken by the Public Health Service, its object being to determine to what extent the rats and other rodents spread disease, such as bubonic plague, and also what amount of damage is done by them in dwellings, barns, warehouses, etc.

Animal Hospital.—The New York Women's League for Animals is to establish a hospital in New York for the treatment of animals of all sorts. A site at the corner of Bond and Lafayette streets has been selected, and a $50,000 building will soon be erected.

Fever Stricken Village.—Troy, Pa., a village with a population of about 1,500, is suffering from an epidemic of typhoid fever. More than 100 cases of the disease had been reported up to October 17.

Births and Deaths in New York.—During the month of August there were in New York State 19,220 births and 11,259 deaths. Of the former 11,525 were credited to New York City, distributed among the different boroughs as follows: Manhattan, 5,787; Bronx, 1,056; Brooklyn, 3,817; Queens, 685; Richmond, 180. The urban births, outside of New York City, numbered 4,274, while the rural localities were credited with the balance, or 3,421. Of the deaths, 5,781 occurred in New York City, 2,766 in the other cities of the State, and 2,702 in the rural districts. Of the total number of deaths, 898 were due to violence. Infantile paralysis assumed the proportions of an epidemic in the western part of the State, and there were 1,046 deaths from diphtheria, as against 236 in the month of July.

Prizes for Babies.—The Australian Parliament has recently voted to grant a prize to the parents of white children born in that country. The measure provided for the payment of twenty-five dollars for each child, but does not apply to the native blacks, or to the Asiatic residents of Australia.

Warning to Tourists.—The Public Health Service reports that there have been a number of cases of smallpox recently at Almera, Spain, a port which is visited by practically all of the Mediterranean steamers, and warns American tourists against landing there. Kobe, Japan, has also been placed upon the black list, as cholera, has reappeared there within the last few weeks. Porto Rico, on the other hand, is believed to be safe, as the plague has been practically wiped out.

Public Health Service.—A board of commissioned medical officers will meet at the Bureau of the Public Health Service, Washington, on November 11, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service. Candidates must be between 23 and 32 years of age, and graduates of a reputable medical college. The examinations are: 1, physical; 2, oral; 3, written; 4, clinical. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Assistant surgeons receive $2,000, passed assistant surgeons $2,400, and surgeons $3,000 a year, and when quarters are not provided additional allowance is made. Further information may be obtained from the Surgeon-General, Public Health Service, Washington, D. C.

Personals.—Dr. John Matthew Connolly, formerly of the Harvard Medical School, has become professor of chemical physiology in the State University Medical College at Portland, Oregon.

Dr. J. William White has been elected emeritus professor of surgery in the Medical Department of the University of Pennsylvania.

A Presentation to Professor Rubner.—A committee of students of the University and Bellevue Hospital Medical College, consisting of Joseph Riss, chairman, Frank J. McLaughlin, John M. Loré, and Henry M. Scheer, waited on Professor Max Rubner, of the University of Berlin, at his hotel, previous to his sailing for home, and presented him with a token in appreciation of his course of lectures at the College, under the Herter Foundation.

The New York Medico-Surgical Society.—At the annual meeting of this Society, held Saturday evening, Oct. 19, at the Hotel Manhattan, the following officers were elected to serve during 1913: *President*, Walter Brooks Brouner; *Vice-President*, William E. Ramsay; *Treasurer*, J. Arthur Booth; *Secretary*, Samuel McCullagh.

Obituary Notes.—Dr. Edward Bond Foote of New York, a graduate of the College of Physicians and Surgeons, New York, in 1876, and a member of the New York State Eclectic Medical Society and of many philanthropic and sociological associations, died at his home on October 12, aged 58 years.

Dr. Walter Savage Whitmore of Oceanic, N. J., a graduate of the New York University Medical College in 1887, and a member of the New

Jersey State and Monmouth County Medical Societies, died on October 11, in the Monmouth Memorial Hospital, Long Branch, where he had been operated on for appendicitis a few days before, aged 63 years.

Dr. St. Mark Fortier of New Orleans, La., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1891, a member of the Southern Surgical and Gynecological Association, and physician in charge of the Louisiana Retreat, died at his home on September 29, after a long illness, aged 47 years.

Dr. Lewis R. Palmer of Baltimore, Md., a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1892, and president of the Maryland Homeopathic Hospital of Baltimore, died in the Hahnemann Hospital, Rochester, N. Y., on October 2, aged 44 years.

Dr. Abraham Joseph Gossett of New York, a graduate of the College of Physicians and Surgeons, New York, in 1909, died on October 5, after a lingering illness, at Monticello, N. Y., aged 25 years.

Dr. Alonzo C. McClellan of Charleston, S. C., a graduate of the Howard University School of Medicine, Washington, in 1880, and founder of the Hospital and Training School for Nurses of Charleston, died at his home on October 4, aged 57 years.

Dr. Thomas Joseph Bennett Dillon of Boston, a licentiate of the Royal College of Surgeons of Dublin, Ireland, in 1884, examining physician to the Boston Board of Health, and president of the Central Council of the United Irish League of Boston, died suddenly in the Massachusetts General Hospital, Boston, while he was undergoing an operation for cancer of the tongue, on October 16, aged 50 years.

Correspondence.

THE VACCINE TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record:

Sir:—In an article published in the Medical Record of September 14, 1912, Dr. Henry A. Craig of New Brighton, N. Y., contributes his observation on the autogenous bacterial vaccine treatment of 300 cases of various diseases, among which 67 cases of pneumonia are included. He states that, "in spite of all treatment, the general mortality of pneumonia remains high—20 to 25 per cent."; and with this standard he ventures to compare the following results which he obtained from the autogenous bacterial treatment of this disease: First series, 47 cases, 7 deaths; second series, 20 cases, 1 death, giving a total mortality of 11.94 per cent.

I believe that Dr. D. B. Lees of London, England, was the first physician who made a practical systematic study of ice application in the treatment of pneumonia, and his first article was published in the *Lancet*, November 2, 1889. Soon after this I became much interested in the subject and made a collective investigation of 400 cases treated in the same way. Dr. Lees' first report comprised 18 cases, without a death. Dr. Freandt, a Finnish physician, treated 106 cases of pneumonia with ice applications, and experienced a death rate of 2.82 per cent. (*Lancet*, August 10, 1892, page 279). My own collection of 400 cases, made about 10 years ago, gave a total death rate of 4.25 per cent.

Now the statement of Dr. Craig, that the general death rate of pneumonia is from 20 to 25 per cent., may be true when this disease is not treated with ice or cold local applications, but it is certainly not true when ice is applied, as is illustrated by the figures just given. The truth is, and this should be recognized by any one who seeks to exploit a new idea concerning the treatment of this disease, that pneumonia, when left to itself, will, under ordinary circumstances, show a natural tendency toward recovery in from 85 to 90 per cent. of all cases, and that any treatment which is incapable of holding the death rate down to the neighborhood of 10 per cent. is not only worthless, but positively mischievous. This statement is not a rash assertion, but is based on the death rate experienced in this disease, when it was treated practically without medication of any sort, as has been done in Europe on a large scale in the past.

It is far from the intention of the writer to advocate the use of any method of treatment in the face of a better one, but, like every other therapeutic subject, this is preeminently a practical question which must be decided entirely on the merits which it is able to show at the bedside, no matter how much theoretical evidence may point in a contrary direction. It would, therefore, advance the service of medicine very much if any one who undertakes to launch a new treatment of pneumonia would investigate the field thoroughly and find what has been done by others in it. He would not fall into the error of believing that the general death rate of pneumonia, notwithstanding all treatment, rises as high as 20 or 25 per cent.; nor would he regard the nearly 12 per cent. death rate of pneumonia as a very strong vindication of the effectiveness of any treatment which had been employed.

Thomas J. Mays, M.D.
1829 Spruce Street, Philadelphia, Pa.

PAIN AFTER NEOSALVARSAN INJECTIONS.

To the Editor of the Medical Record:

Sir:—In the Medical Record of July 27, 1912, I presented a brief report of neosalvarsan, with a method of intramuscular injections with the view of reducing the element of pain to a minimum. Since the publication of that paper further studies have made clear the reason for the occurrence of pain in some of the injections that have been made by myself and others, and I beg you will give me this space to mention them briefly.

It seems to be imperative that the glycerin and the betaeucain or alypin solution be freshly prepared. In a large number of injections this observation has been made, and the pain has been almost nil when the glycerin has been freshly sterilized and the anesthetic solution freshly made.

The method of intramuscular injection does not seem to be indicated in patients who have already received intramuscular injections of mercury or of some other arsenic preparations. In such cases infiltrations are the rule, and it appears that the injection of neosalvarsan acts as an irritant to these masses and sets up an inflammatory reaction which is very painful. I do not know any way of avoiding pain in these cases; the intravenous method is indicated.

Abr. L. Wolbarst, M.D.
113 East Nineteenth Street, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPENING OF THE SCHOOLS FOR WINTER SESSION—INSURANCE, RESIGNATION OF CLUBS, AND CHARITIES—DEPUTATIONS TO MR. LLOYD GEORGE—PROVISIONAL REGULATIONS IN FORCE—PLAGUE—OBITUARY.

London, October 4, 1912.

The winter session was opened at the medical schools on Tuesday. At several the traditional method of marking the occasion by an introductory lecture at which former students were wont to assemble has been discontinued and a dinner conversazione, or something, substituted. I think it was old Barts which set the example some years ago. I am disposed to agree with the regrets often expressed by not a few at the loss of the time-honored function. The distribution of prizes takes the chief place in the program at some schools, and with it a short address from the celebrity who undertakes the duty, but it went just as well with the inaugural lecture. The Lord Mayor undertook the distribution at St. Mary's Hospital, and as he (Sir T. Crosby) is a medical man, was at once in touch with his audience. He urged the importance of the work of corporate and municipal bodies and thought the profession had neglected golden opportunities by not serving upon them. They would become leaders because they knew what was wanted for the health of the people. Such questions were part of their education and they would know more about them than engineers and that sort of people. It was difficult to keep out all reference to politics. "When I became Lord Mayor I put my politics under the table and luckily have not bent down to pick them up. But I have received many earnest applications from brother professionals, who thought, with justice I think (but that must be recognized as *sotto voce*) that they were not having fair treatment from the government. But they have taken that matter into their own hands, and I think they will succeed." The speech was punctuated with applause and the chairman, Dr. Philips, in proposing a vote of thanks which was carried with acclamation, observed that the Insurance Act was pushed through without the profession being consulted upon it or any of its details. The Lord Mayor afterwards opened the new casualty department and spoke of its importance to the hospital.

The Lord Mayor put in another appearance on the same day in connection with the celebration of the opening session; for he presided at the dinner of St. Thomas's Hospital and contrasted its present position with that of the old site where he received his own education. Then he repeated his view that medical men should take up county and municipal work. He looked upon it as a duty for them to do so and let those who controlled affairs know their worth. Their education would take them to the top and win them the respect of their associates. They must also vindicate the rights of the profession.

It was announced that a generous friend had handed the treasurer a cheque for £20,000 toward a new out-patient department.

At the Middlesex Hospital Dr. Lazarus Barlow delivered the address which he entitled the "Genius of the Infinitely Little," a phrase which excited some speculation as to what he intended to convey by it. Referring to the minuteness of the agencies at work in the functions of life he spoke of the virulence of bacteria, their extreme variation, some strains being killed off and others surviving adverse conditions. The modification of type depended on the survivors. The production of disease, its non-production, and the exaltation or depression of virulence, he cited as examples of the infinitely little. Passing on to radium emanations, he thought the story one of nature's masterpieces of satire. The alchemists strove to change the baser metals into gold, for they knew not that nature for untold ages had been turning the relatively common metal uranium into radium, 170,000 times more costly than gold. The dream of the alchemists was fulfilled and more, but with an almost diabolical contempt of man nature was endowing radium with the property of ceaseless change and decreeing that the transmutation should continue till it became lead, worth 2 pence a pound. True, time was not an object with nature and she would take a couple of thousand years to turn an ounce of radium into ½ an ounce of lead wherewith to mend a burst water-pipe. That only made the satire more pungent, for the existence of radium was discovered when there was plenty of lead and to spare. With all the minuteness of the rays shot off by radium bacteria might be destroyed by them. It was anticipated that cancer cells might be so destroyed. The tubercle bacillus and anthrax spore, extremely resistent to germicides, were killed by alpha and beta rays. Dr. Barlow said it might well be imagined that in the not very distant future radium would be used in the treatment of bacterial diseases. They already had indications that in smaller doses the emanations were stimulant. If so, what meant the presence of minute amounts of radium in the human body? Having mentioned some other speculations as to the genius of the cell and the infinitely little he turned to the new students and told them that the honor of the medical profession had been won for them by the infinitely little ones in the past and prayed them in their turn to hand on the torch undimmed and manifest the genius of that infinitely little by doing their duty always.

At Charing Cross Lady Mary Glyn distributed the prizes and the Bishop of Peterborough delivered an address in which he urged the students to join the shooting club so as to prepare for the defence of the Empire and the ideal of national life. The existence of their country almost depended on the universal military service proposed by Lord Roberts. As to the little black spot which had come into their lives in the Insurance Act it must be amended. He believed promises of this had been made, but it would be well for the originators to begin the amendment.

At St. George's Mr. H. B. Grimsdale gave the inaugural address and distributed the prizes. His subject was the "Duty of the Medical Citizen." Having reviewed the development of medicine as a science and an art he spoke of the blow struck by the government which might throw it back a century or more. The chancellor had exhibited his ignorance of the first requirements of modern medicine and seemed to fancy doctors were engaged in a guessing competition with numbered bottles corresponding with numbers given to diseases. The government were generous to working men and even to quacks —but at the expense of medical men.

The Insurance Commissioners have decided to divide England into nine inspectorial districts each with a divisional officer permanently resident in the chief town. There will be 277 new officials. Some

have been appointed. Of these, 8 are said to have special knowledge of Friendly Society work and 5 to be connected with trade unions.

Resignations of clubs continue to be sent in as do appointments on voluntary charities. The staff of the Royal Surrey Hospital intimate that they cannot treat insured persons gratis as at present when the act comes into operation in January. In most Surrey towns the profession seems unanimous. In the Manchester district I hear 240 club appointments have been relinquished as from January 15. In South Wales a system has long prevailed of contributions for medical officers being deducted from wages. The act would still apply and so double payment be exacted. The contracts are therefore being terminated with a view to a rearrangement. In the Liverpool district there are about 600 practitioners and of these 471 have already resigned contract work.

In Northampton 20 and in the county 150 have resigned. From Norfolk and Suffolk similar reports arrive. The unanimity of the profession has never been so marked. Every morning brings one similar decisions, and it seems useless to give further examples. It is much the same with regard to honorary appointments at the voluntary hospitals and charities. Some of these have already had subscriptions discontinued. Thus the North Stafford infirmary, largely supported by workmen, has been compelled to suspend structural extension towards which the public had freely subscribed.

On Wednesday Mr. Lloyd George received 18 medical members of the insurance advisory committees. These gentlemen are those who declined to resign when the majority did. There were at first 58 medical members appointed by the Insurance Commissioners and of them 38 resigned very soon when the opinion of the profession found distinct expression. The 20 who refused to follow, of whom Sir Clifford Allbutt has been the spokesman, were of opinion that they could serve their brethren better by remaining, and Sir Clifford, for himself and colleagues, has since testified to the careful and favorable consideration accorded to their representations, but said cardinal questions such as remuneration must await the return of the chancellor from his holiday. Wednesday's interview was arranged accordingly and the deputation submitted that in the public interest additional financial provisions should be made so as to allow fair remuneration to medical officers. The chancellor thanked the deputation for the support they had given him so far by remaining on the advisory committees and continuing their great public service by advising him at the present juncture. He promised to confer with his colleagues as soon as possible and hoped to be able to state their decision in the course of the week beginning on October 14.

This result is only what has been pretty generally anticipated from the various suggestions put forward in political and medical circles. It has long been believed that Mr. Lloyd George would be glad to see a way out of his trouble and was only waiting for a good opportunity to yield. He is not likely to get a better plan than these medical men offer. It is true they are in opposition to the mass of the profession and have been called many hard names. But they mean well and I am content to say they are out of tune with the majority. If they extract enough from the government to make fair remuneration other differences may perhaps be forgotten.

To-day the chancellor is receiving another deputation from the advisory committee. This is from the representatives of the insured persons.

Meantime there has appeared what may perhaps be a counterstroke. No less than the text of the provisional regulations made by the committees of the English, Welsh, and Scotch Insurance Commissioners. It was issued last night and comprises 59 sections (most of them with subsections), 4 schedules, and an appendix. It is prefaced by a statement that "on account of urgency," though provisional, these regulations are to come into operation immediately. It looks as if intended to obtain a determination to proceed whatever the opposition. The document would fill a number of the MEDICAL RECORD and is such as might have been issued if all parties were agreed and the scheme actually at work. Of course busy practitioners cannot digest it in a day, and though it looks fair enough in some respects it is desirable they should carefully scrutinize every phrase. It deals with every department, requires every committee for a county or borough to make arrangements for the treatment of insured persons, to estimate the cost, to determine conditions on which to invite practitioners to serve (after consultation with local medical committees), to decide methods and rates of remuneration, questions as to mileage, income limit, and many other points. All particulars are to be embodied in draft agreements and submitted to the commissioners as must every act of the local committees. When no agreement can be made the commissioners will take the matter into their own hands. It must be remembered their ordes have the force of the act itself and the possibility of the abuse of such power is obvious.

A case of plague has occurred on board a vessel in the River Tyne, which arrived on September 10 from Hamburg, and an apprentice was attacked the same day. He was taken to the floating hospital as suspected typhoid. Next day the medical health officer of the district examined his blood and diagnosed plague. He died on the 16th. A post mortem was made and the diagnosis has since been confirmed in the laboratory of the local government board. It has been ascertained that two other cases occurred on the same vessel before arriving at the Tyne. Of course every precaution has been taken to prevent the spread of infection.

Inspector General Sir Herbert M. Ellis, K.C.B., R.N., died on September 30, aged 61. He qualified at the two colleges in 1873 and joined the navy in 1875. He served in the Royal Marine Artillery through the Egyptian campaign of 1882 and was at Kassassin and Tel-el-Kebir, received the medal with clasp and star and promotion to staff-surgeon. In 1893 he was fleet surgeon on the *Victoria*. Next year he became Inspector General and from 1904 to 1908 was Director General of the medical department of the navy. In 1906 the Royal College of Surgeons elected him to an honorary fellowship. He was Honorable Physician to King Edward and to King George. He was also a magistrate for Carnarvonshire. In 1907 he received the Order of the Bath.

Dr. Edward Woakes, late senior aural surgeon to the London Hospital and surgeon to the Throat Hospital, died on September 30, aged 75. He was M.D., London, 1863. His book on "Deafness, Giddiness, and Noises in the Head" reached a fourth edition in 1896. He had written on "Nasal Polypus in Relation to Ethmoiditis" in 1887 and on "Post-Nasal Catarrh" as early as 1884.

Dr. John Knight, medical health officer for Scar-

borough, died September 16, at the early age of 37. He graduated at Glasgow M.B. with honors in 1896; M.D., 1902; D.P.H. Cantab., 1898. He had been assistant medical health officer at Glasgow and had lectured on forensic medicine and public health in the university. Seven years ago he went to Scarborough and his reports were always valuable. He investigated with great care the infantile mortality from 1876 to 1905. He had a serious operation performed three months ago for malignant disease, but has succumbed.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

PLAGUE IN MANILA AND ILOILO—POSSIBLE INTRODUCTION IN RICE—UNSATISFACTORY MILK SUPPLY—DIMINISHING DYSENTERY—PRISON HYGIENE—PERSONAL.

MANILA P. I., August 30, 1912.

DURING the past few weeks there have been a number of additional developments in the plague situation in the Philippine Islands. So far, however, nothing alarming has occurred. There have been seven deaths in Manila and three in Iloilo.

During the week ended August 24 two additional cases were reported in the city of Manila. One of these occurred in the person of a schoolboy who resided at 352 Calle Echague, and who had a history of having lived, six days before he was taken ill, at 15 Calle Villalobos. It may, perhaps, be remembered that two of the previous cases that occurred earlier in the month were in the same street and block, viz.: 27 and 37 Calle Villalobos, respectively, and that they were also in schoolboys. The other case occurred in the person of a Chinese barber who lived at 417 Calle Poblete, which is within a block of where the first case occurred on June 7, 1912. The rat-catching efforts have now been concentrated upon these two apparently infected centers, but, so far, no plague-infected rats have been found, so that the origin of the infection is still unknown.

All cases have occurred in persons who were permanent residents of the city, and who had, apparently, no connection with the shipping, and were in sections of the city which are well removed from the water front. Both of the last-mentioned cases were of the septicemic type. In the case of the Chinaman, the disease had proceeded far enough to be in reality pyemic in character. Numerous abscesses were found in the lungs, liver, and in the skin of certain portions of the upper extremities. A small, hard papule was found on the left foot, which might possibly have been due to a flea bite, and a specimen obtained by cutting into the papule resulted in a positive culture for plague. The left femoral bubo, however, did not differ from the buboes in other portions of the body, and was regarded as being of the secondary type.

In addition to the cases reported in Manila, there were also two cases at Iloilo, both of which have been confirmed by laboratory methods. This was the first reappearance of plague in Iloilo since the case which occurred on July 5. The Bureau of Health sent the Assistant Director of Health, Dr. Carroll Fox, to Iloilo, to take charge of plague suppressive measures. He took with him Dr. Ruediger of the Bureau of Science to do the necessary autopsies and laboratory work. It is the intention to begin an active rat-catching campaign and to carry out as much rat-proofing as practicable.

Owing to the great shortage of rice in the Philippine Islands, there have been enormous importations of this staple brought to the ports of entry in the Philippines, and, as much of this rice comes from plague-infected districts, it has been suspected that possibly some plague rats or fleas might have been imported with it. An investigation of this matter showed that rice from Saigon could easily be placed on the market in the Philippines within a period of seven days from the time that it left Saigon, and, in accordance with the experience of the Indian Plague Commission, it would even be possible for plague-infected fleas to be introduced through such importations.

The cargo that comes to the Philippines from Japan and China is of such character that it might easily harbor rats, and it would seem most likely that the disease may have been introduced in this manner. On account of the fact that all cases have occurred among permanent residents, and in persons who have not been outside of the islands for years, it does not seem probable that the disease could have been introduced through human beings.

In spite of the constant efforts of the Bureau of Health, the quality of the fresh milk that is placed on the Manila market still leaves much to be desired. One of the reasons for this is, that the cows from which a large portion of the milk is obtained are kept outside of the city limits, and are the property of persons who have, probably, only one cow and that has no fixed place of abode, for which reason it is impracticable to enforce regulations, such as could be done in the United States. Much of the milk, also, comes from the caraballa, or water buffalo. The fats and some other important ingredients in this milk are often double that found in cow's milk. In order to imitate cow's milk, this is frequently diluted one-half, or more, with water. The proteins are then in disproportion, so rice flour is added. If the fats have then been too greatly reduced, cocoanut oil is sometimes added. The resulting mixture is a most insanitary substance. One specimen of milk examined contained 62,391,600 bacteria. Owing to the impracticability of effectually regulating the dairies of so many small milkmen, it is proposed to establish a central pasteurizing plant and require all persons who desire to sell fresh milk in the city to have their milk pasteurized before it is offered for sale.

Since the onset of the heavy rains there has been a constant decrease in the number of cases of bacillary dysentery, and judging by the experience had in former years the disease will probably soon disappear. It either prevails more extensively this year than formerly, or perhaps its presence came more sharply to notice on account of the fact that there was no cholera to absorb all the attention. Laboratory examinations made of stools from cases from many of the provinces, invariably resulted in finding either the Flexner or the Shiga type of organism.

As a result of the recent inspection made of the prisons throughout the provinces of the Philippine Islands, it developed that there was no systematic form of daily exercise for prisoners being carried out. This matter was immediately taken up with the prison officials and arrangements have now been completed to have regular, fixed, physical exercise introduced in all of the jails. At the same time, recommendations were also made, and are being placed into effect, for better ventilation, drainage, food, etc. The improvement in the provincial

jails as compared with five years ago is most noteworthy, and their condition is beginning to compare favorably with similar institutions in the United States.

Dr. E. R. Gentry of the Army Board for the Study of Tropical Diseases has been appointed instructor in histology in the College of Medicine and Surgery, University of the Philippines.

Dr. Elbert Clark, Associate Professor in Anatomy in the College of Medicine and Surgery, University of the Philippines, has been made vice dean in that institution.

Drs. Richard P. Strong and Vicente de Jesus have been appointed by the Philippine Government as delegates to the International Congress of Hygiene and Demography, at Washington, D. C.

CANADIAN PUBLIC HEALTH ASSOCIATION.

Toronto, September 20, 1912.

The Canadian Public Health Association, which had its inaugural meeting in Montreal last December under the presidency of Dr. T. A. Starkey, professor of hygiene at McGill University, Montreal, and under the direct patronage of their Royal Highnesses the Duke and Duchess of Connaught and of the Princess Patricia, held its second meeting in Toronto on September 16, 17 and 18, under the presidency of Dr. Chas. A. Hodgetts, of Ottawa, medical adviser to the Canadian Commission of Conservation. The meeting this year was again a complete success, nearly 300 members registering at the place of meeting, the medical buildings of the University of Toronto. Perhaps no association of the kind has ever begun under so favorable auspices or has since progressed with so great rapidity. The Canadian Public Health Association now numbers more members and has larger funds than the American Public Health Association. This is a convincing proof that the public health conscience of Canada has been aroused and that the general public is taking an intelligent interest in the health of the community at large. The fact is recognized that the good health of the people is of the first importance from every point of view and that without a healthy race no nation can prosper. For this recognition the far-seeing policy of those responsible for the control of the association is to be thanked. Membership of the association is open to all, and indeed laymen and laywomen are urged to become members. At the recent meeting almost all grades of society were represented and took a keen interest in the proceedings and discussions.

The first paper read struck the keynote of the meeting, that the rush of immigrants and the rural population to towns must be checked if the country should continue to progress. Dr. P. H. Bryce, Ottawa, Superintendent of Immigration, and an acknowledged authority on the subject, read the paper, which did not fail to impress his hearers with the gravity of the situation. It should particularly interest American readers, for it dealt with a situation almost exactly similar in Canada and America. Dr. Bryce asks the question, How shall Canada save her people from the physical and mental degeneracy due to industrialism as seen in the great cities of older civilizations? How long can a country essentially a producer of raw material by virtue of geographical location and extent of territory still largely undeveloped continue normally to develop and prosper when it has shown a displacement of rural population never witnessed before in the history of any people and an increase in urban population, rapid even beyond the palmiest days of the United States immigration? Dr. Bryce suggested remedies for the existing state of affairs into which there is no space here to enter.

A paper of very marked interest was read by Dr. Bruce Smith, Inspector of Prisons and Charities for Ontario. Dr. Smith discussed hospitals and their relation to the community and to public health. Referring to municipal hospitals, the speaker declared that there was no room in Canada for more hospitals solely under municipal control. He pointed out that the establishment of a municipal hospital destroyed the philanthropic spirit of the people. Local philanthropy was never exercised for such hospitals and persons would as soon think of giving a contribution to the city hall or to the street railway as to the hospital under municipal control and management. Furthermore, he went on to say that ward politics were decidedly incompatible with hospital management. The contrast between municipal hospitals and those directed by a local board was most striking. There was always a discordant note from the executive side of the municipal institution. Everywhere were seen the finger prints of the politician; the ward boss and the political heeler exerted their baneful influence without check or scruple. Fortunately, they had not in Canada the experience which had been so expensive in some American cities during the past few years. Dr. Smith was of the opinion that a private patient should be permitted to have his own physician or surgeon attend him if he wished; the semi-private patient should have the same privilege if he contributed to the hospital a sum equal to the cost of his maintenance there; the patients in the public wards should be attended by members of the staff. To permit patients in the public wards to have their own medical men would cause endless confusion. Hospitals should be for the treatment and care of the sick, for the instruction of students in medicine and surgery, and by the prosecution of research for the furtherance of medical science to the benefit of humanity.

Dr. Chas. A. Hodgetts, of Ottawa, medical adviser to the Canadian Commission of Conservation, was especially insistent that public health matters should be dealt with by the national government. A national government should give direct attention to public health under a bureau, because such a government would have at its command greater resources for the study of the relation of its people to their environment, animate and inanimate, than the provinces or municipalities. Dr. Hodgetts referred in particular to the inspection of the thousands of immigrants entering the country. If the people of the country were satisfied with a medical examination of several hundred persons, often speaking a foreign language, in a few hours by one or two medical men, then they were willing to face a danger which he believed would show itself in the near future; indeed, it was manifesting itself already. This question alone, he thought, provided sufficient argument to justify the establishment of a federal bureau of health. Moreover, there remained to be evolved a scheme for the co-ordination of public health work on imperial lines. It was necessary that every nation of the empire should play its part in building up the highest type of citizens and provide men and women physically fit to hold their own in the commercial struggle which

was not likely to become less strenuous as years passed by. Dr. Hodgetts has always been a strong advocate for good housing, and he declaimed in vigorous terms against the manner of building most in vogue in Canadian cities. He said that it was a disgrace to Canada that immigrants of the lower type should be permitted to live in the cities of Canada under worse conditions than prevailed even in their own lands.

An address on public health affairs was given on the evening of September 16 by Dr. W. A. Evans, late Commissioner of Public Health of Chicago. In the course of his eloquent address Dr. Evans mentioned the difficulty in present circumstances of further reducing the death rate from communicable diseases. He said that in England, however, certain clauses of Lloyd George's Insurance Act would probably reduce tuberculosis by 20 per cent. Moreover, it would encourage the treatment of maternity cases in hospitals and thus reduce the number of newly born infants and of women. It would penalize municipalities whose people were compelled to pay high insurance rates by reason of insanitary conditions and it would deal with manufacturers whose employees suffered in a similar manner because of unhealthy factory surroundings. Health departments could lead the people in dealing with overcrowding in large cities and the housing of the poor. The public could not afford to have the people live under insanitary conditions, nor could they afford to have children brought up amid such surroundings. There had been, he said, in the past a disregard for what actually counted—healthy and efficient men and women. Now there was a demand from manufacturers and business men for efficient laborers capable of producing goods to compete in the markets of the world. Practitioners of preventive medicine could help to meet this demand.

In the section of engineers and architects several excellent papers were read on filtration, sewage disposal, and housing problems. Prominent among these was one by Mr. Race, bacteriologist of the city of Ottawa, on Toronto's filtration plant. In the discussion that followed this paper Dr. Bryce made some pertinent remarks on hypochlorite of lime as a purifying agent for sewage. He said that as an old chemist he could not see how chlorinating sewage was going to destroy the pathogenic germs. To his way of thinking it should not be called hypochlorite treatment, but hypocrisy. The view is now taken by several authorities that too much reliance is now being placed on the purifying effects of hypochlorite on water and sewage. Instead of employing the substance for purifying water in emergencies it is being largely used as a routine mode of treatment. It is argued that filtration should be so efficient that in the usual course of events no other agent should be needed, and ergo that hypochlorite should be relegated to its proper place as an emergency measure. It is pointed out that in Europe by means of efficient systems of filtration typhoid fever has been practically eliminated and that hypochlorite is only employed when filtration is inefficient.

In the section of military hygiene some good papers were read, notably by Col. G. Carlton Jones, P.A.M.C., Director General Medical Service, Canada, on the sanitation of a besieged city, and by Major Lorne Drum, P.A.M.C., on the militia as a factor in public health.

A very instructive part of the program and one that appealed to everybody was the section on social workers. The section was presided over by Dr. Helen Macmurchy, Toronto, and dealt with acutely pending social problems. The question of the prevention of social misery provoked much debate, and individuals from all grades of society took part in the discussion and suggested various means for remedying the present unfortunate state of affairs in all cities of the world.

The programme of the meeting was long and exhaustive and only the principal points have been touched on here. Mention, however, should be made of papers read on tuberculosis by Drs. J. H. Elliott and G. D. Porter, Toronto.

At the closing meeting the election of officers took place. Dr. J. W. S. McCullough, chief medicl officer of Ontario, was elected president, and Regina, Saskatchewan, was chosen as the next place of meeting. The executive committee is as follows: The president; the treasurer, Dr. G. D. Porter, Toronto; the secretary, Major Lorne Drum, Ottawa; Prof. John Amjot, Toronto; Col. G. C. Jones, Ottawa, and Dr. C. A. Hodgetts, Ottawa. Two important resolutions were passed before adjournment: First, the organization urged the formation of a Federal Department of Public Health, and second, a resolution was passed to urge upon the Dominion Government the need for more stringent laws with regard to preventing the pollution of waters which are or may be used as the sources of a public water supply. Shortly before the meeting closed the very sad announcement was made that Mrs. Starkey, wife of Dr. T. A. Starkey, professor of hygiene at McGill University, Montreal, had died somewhat suddenly. Prof. Starkey was well known to members of the association, respected for his wide and intimate knowledge of all matters concerning public health, and liked for his pleasing personality. On his own account therefore the sympathy of all the members went out to Dr. Starkey. To those who had been privileged to know Mrs. Starkey and had had the opportunity for appreciating her whole-hearted kindness and lovable disposition, the news came as a personal shock and by them Dr. Starkey was sympathized with more keenly and with a more intelligent understanding of what her passing meant to him. A resolution was made at the meeting condoling with Dr. Starkey.

The meeting was successful from the scientific, practical, and social standpoints. The city of Toronto extended her hospitality and some individual citizens gave special functions for the benefits of the visitors. Sir Edmund Osler gave an at-home, Lieut. Col. and Mrs. E. Gooderham gave a musicale, and there was also given by the association itself a dinner and smoker.

2. Norway Revisited. C. Kent Austin.
3. The Effect of the Pasteurization of Milk on Babies. J. L. Morse.
4. A Case of Hemianopsia Due to Vascular Disease. H. P. Greeley.

1. **Surgical Aspects of Fat.**—J. M. T. Finney presents a general review of the subject of the relationship of fat, in its various manifestations, to surgery. In the first place, fat may have a definitely beneficial and conservative effect. One has but to recall the classical picture of the thin, neurotic visceroptotic female patient. By keeping

the latter in bed for a number of weeks and improving her nutrition, one may succeed in producing a deposition of adipose tissue, hoping thereby to anchor the floating kidneys, and splint the other too mobile viscera. On the whole, however, the effect of fat is detrimental rather than beneficial to the work of the surgeon, for there are many ways in which its presence is of real disadvantage in case of a surgical operation. It is a tissue feebly resistant to bacterial invasion. It does not heal readily. It is soft and friable and easily torn and injured, leaving particles of loose fat or oil globules between the adjacent surfaces of the wound, and thereby interferes with wound healing. Where the subcutaneous fat is present, in large amount, frequently to the thickness of several inches, particularly in the case of the abdominal wall, it interferes materially with the manipulations of the surgeon, and may necessitate a very considerable lengthening of the abdominal incision. Surgical or non-surgical traumatism of fatty tissue may lead to fat embolism. Intoxications of non-bacterial nature, arsenic, antimony, carbon monoxide, mineral acids, chloroform, phosphorus, etc.; states of malnutrition: and severe anemias, primary or secondary, lead to fatty degeneration. Necroses occur in fatty tissue in addition to the usual causes of failure of blood supply and irritation in three striking forms: (1) One resulting from acute pancreatitis through the liberation of fat-splitting enzymes seen so commonly in the omentum as to be pathognomonic and exceptionally also in the subcutaneous fat. (2) That peculiar fatty necrosis exhibited by individuals manifesting carbolic acid idiosyncrasy in gangrene and characterized by tough, dirty, yellow sloughs. (3) That resulting from long continued application of ice to the abdomen as in the case of the ice bag for appendicitis.

3. **Effect of Pasteurization of Milk on Infants.**—J. L. Morse notes that there is no unanimity of opinion among the leading pediatrists of this country as to the effect of the pasteurization of milk on its digestibility and as to whether it renders milk less suitable for the feeding of infants. The only conclusions which seem to the author to be warranted from his study of the subject are as follows: It is impossible to determine from the evidence at present available whether or not babies fed continuously on pasteurized milk thrive as well as those fed on raw milk or whether or not the continuous use of pasteurized milk predisposes to the development of the diseases of nutrition. There is sufficient evidence to show, however, that if the continuous use of pasteurized milk is injurious to babies, its possibilities for harm are much less than those of bacteria. All but the cleanest milk should, therefore, be pasteurized before it is given to infants. There is, on the other hand, sufficient doubt as to the innocuousness of pasteurized milk to justify the avoidance of pasteurization whenever the character of the milk warrants it. Finally, one's knowledge of the whole matter is extremely incomplete and unsatisfactory. The question as to the effect of the pasteurization of milk on the nutrition of infants can be settled only by a much more careful and extensive study of the whole subject, both in the laboratory and clinically, than has hitherto been undertaken.

4. **Hemianopsia Due to Vascular Disease.**—H. P. Greeley reports the case of a fisherman, aged 57 years, who had never suffered from any serious diseases, syphilis or gonorrhea, and had never had any previous attack of paralysis or weakness. Three days before examination the patient suddenly noticed some numbness and weakness in his right leg. This passed off almost immediately but was accompanied by tingling and numbness in the right arm which persisted to a slight degree. At the same time he noticed that he became "right" blind and could see no objects toward the right without turning his head. These symptoms were accompanied by a little dizziness and headache over a period of a couple of days. He had no pain and no other symptoms of constitutional disorder; no nocturia; no vomiting. His habits were good as to alcohol and tobacco. Examination of the field of vision showed absent visual power in the right half of both eyes. He could not see his nose at all with his left eye and could not see an object with right eye till it was nearly directly in front of him (with eye directed forward). Ophthalmoscopic examination showed no retinal changes. The retinal arteries were like fine silver cords. The pathological lesion in this case the author judged to be a small hemorrhage or thrombosis in the posterior part of the left internal capsule, permanently affecting the optic tracts.

3. **Errors in Treatment of Senile Cases.**—I. L. Nascher enumerates the chief sources of error into which the physician may fall in the diagnosis of senile cases. These sources of error are as follows: (1) Normally degenerating senile organs may present manifestations which simulate symptoms of disease. (2) The manifestations of senile degeneration may be so pronounced as to mask the symptoms of a disease. (3) Symptoms may be so obscure as to be unnoticed or uninterpretable. (4) There may be a misinterpretation of numerous symptoms which, taken collectively, form apparently a symptom-complex. Where such diagnostic errors are made, errors in treatment naturally follow. Mistakes in treatment may also occur through ignorance or neglect of the pathological and clinical differences in diseases occurring in maturity and in senility; of the tendency of diseases to involve allied organs, either directly or through the inability of an allied organ to accommodate itself to the altered function of the diseased organ; of the greater resistance to some pathogenic factors and the lessened resistance to others: and also through ignorance or neglect of lessened innervation, mental depression, exaggerated symptoms, etc. These all fall under the head of errors in diagnosis. A more prolific source of error in senile cases is ignorance of the action of drugs and other therapeutic agents upon the degenerating organs, and neglect of the secondary effects of drugs which in the aged are often more pronounced than the primary or desired effect. A universal error made in dealing with senile cases is the attempt to restore or *cure* normal degenerations. Digitalis is a particularly dangerous and unreliable drug in senile cases. The tincture given *per os* does not manifest any effect upon the circulation until after twenty-four hours; the action of the drug is cumulative; and the latter is useless in an emergency.

4. **Complement Deviation Reaction in Gonorrhea.**—J. A. Gardner and G. H. A. Clowes find that the complement deviation reaction for gonorrhea, when carried out with a polyvalent gonorrheal antigen by the method recommended by Schwartz and McNeil, gives remarkably reliable results and permits of a specific differentiation, even in the presence of syphilis and other diseases exhibiting complement deviation phenomena. The authors' cases giving +++ or ++ gonorrheal reaction, were all undoubted cases of gonorrhea; although it appears probable that in certain severe chronic cases the reaction may persist for some time after a cure has been effected. The cases giving a negative gonorrheal reaction (with

one exception, previously referred to, and acute cases within twenty-one days of infection), failed on examination to show diplococci, and may be considered to be probably free from the disease. The cases exhibiting a ++++ Wassermann reaction for syphilis gave for the most part a negative reaction in the gonorrheal series, and when a strong positive gonorrheal reaction was obtained there is little doubt that gonorrhea was, or had been present. It is remarkable that in the authors' series of 185 cases, seventy of which exhibited a strong reaction in the gonorrhea or syphilitic series, only seven cases, or ten per cent., gave a strong reaction in both. A slight reaction is of unquestionable value in diagnosis, but, as in the case of a slight Wassermann reaction for syphilis, should never be considered final. The authors declare that they have up to the present time failed to find a single normal individual exhibiting a definite reaction when a test was made with the gonorrheal antigen.

6. High Frequency Currents in Eczema.—E. G. Charbonneau reports a case of intractable universal eczema in an infant. The disease had resisted many different forms of treatment. There was a marked diminution in the excretion of urea, which fact indicated an error in metabolism. Malnutrition, together with an alkaline urine being in evidence, the author subjected the patient to the powerful stimulating, as well as eliminative effects of the low potential, high amperage, high frequency currents. Lemon juice was given from three to four times daily. The local manifestations were brought under control with the topical application of the high potential currents, alternating with from four to six second exposures to the *x*-rays. Improvement in the condition of the infant's skin began almost immediately after the first treatment and recovery was complete within two weeks.

7. Traumatic Separation of Epiphyseal Beak of Tibia.—G. H. Rhodes notes that the upper end of the tibia is developed usually from two centers, one for the diaphysis, and one for the epiphysis. The epiphyseal center appears at about twelve years of age and unites with the diaphysis at about the twentieth year. The structure destined to form the tubercle of the tibia is usually evolved from the epiphysis by a downward growth, covering the upper and anterior aspect of the head of the tibia, and from its resemblance to a bird's bill, is called the tibial "beak." In some instances, however, this beak, instead of being developed from the epiphysis, develops from a separate esseous center. A total tearing away of the tubercle of the tibia is recorded as a very rare injury. Stimson states only nine cases to have been recorded. A more common lesion is the separation of the beak, or what is termed a "starting" of the epiphysis, by a sudden violent pull on the patellar tendon. The probable reason for the incomplete nature of the fracture or separation, is that the tubercle of the tibia is not the sole point of insertion of the patellar tendon. The author reports a case of this rare condition which came under his observation.

8. X-Ray Treatment of Tuberculous Glands of Neck.—M. Strunsky states that statistics show that only fifty-seven per cent. of cures follow the usual surgical operations for tuberculous adenitis, and that in about twenty-five per cent. of these cases there is a local recurrence. Only the enlarged glands are removed, while small, deep seated but infected glands remain. Scars which are often unsightly follow operations. Many cures of cases of tuberculous adenitis by means of the application of the *x*-rays have been reported of late. The author concludes that a scientific trial of *x*-ray treatment both before and after operations is advisable in every case of tuberculous gland of the neck.

4. Effect of Iodides in Arteriosclerosis.—J. A. Capps concludes that iodides in therapeutic doses are not active vasodilators and when long continued do not materially affect blood-pressure. Iodides do not alter the viscosity of the blood to any marked degree. The iodides probably owe their beneficial influence in syphilitic arteriosclerosis to the absorption of the cellular exudate in the arteries. The absorption may be brought about by the formation of a proteolytic ferment which is created by the union of iodide with antibody, and which has a selective action on the luetic cellular exudate. It is possible that this selective digestive action may be operative to a lesser degree on the cellular exudate in arteriosclerosis due to other causes than syphilis.

5. Duration of Action of Digitalis.—C. Eggleston emphasizes the facts that the elimination of this drug is slow and that after the disappearance of the traceable signs of its action there remains in an active state in the tissues a very large part of the total digitalis absorbed and acting prior to the cessation of its administration. This period of digitalis action, which cannot be definitely shown to exist by means of tracings or even by clinical signs in the majority of patients, may be termed the period of latent action. It is represented by the slowly falling line below the level of obvious action, either therapeutic or toxic, and its duration is of uncertain length. The author concludes that the drug is more or less firmly fixed in the tissues, probably of the heart, and continues its action in proportion to the quantity present. The return to action in response to a smaller second dose is the summation of the drug fixed in the tissues and that which is subsequently introduced. The phenomena of the persistence of digitalis action is due, therefore, not to the lasting effects of an injury to the heart, but to the actual presence of the drug in the tissues in active form.

6. Antityphoid Inoculation of Nurses.—L. H. Spooner finds that the frequent injections of small amounts of a low-virulence vaccine cause slight inconvenience. They seem to produce a protection among nurses, who are eight times more liable to typhoid fever than the average individual. Their morbidity, under ordinary conditions, is 1.4 per cent., or 19 cases among 1,361. Case morbidity among the uninoculated nurses in hospitals is nearly nine times greater than among the inoculated, subject to similar conditions. No permanent untoward effects have arisen from over 5,000 injections. The blood-picture indicates a certain protection, lasting at least two and a half years. The use of this means of protection has been shown to be safe in two epidemics and very efficient in at least one of them.

7. Usefulness of Antityphoid Inoculation.—F. F.

Russell describes the results obtained in the United States Army with the use of typhoid vaccine, which has been employed in about 400,000 doses. The vaccination has been obligatory and very thoroughly carried out, thus obviating any criticisms that it has been done only on a selected class who would be likely to avoid exposure. Typhoid fever has been practically abolished in the army, only five cases occurring in the first four months of the present year, and only one in a person who had been vaccinated. The other cases were in newly enlisted recruits. The author believes that antityphoid vaccination has an extensive field of usefulness in civil life, especially in hospitals and other institutions, in industrial establishments, in camps of laborers, and among persons patronizing summer resorts or traveling.

10. **Mode of Infection in Poliomyelitis.**—S. Flexner advances the view that the nasal mucous membrane is the avenue of ingress and egress of the virus of this disease in the human species. The virus passes with readiness and constancy from the intact or practically intact mucous membrane of the nose to the central nervous system, and this, next to the direct inoculation of the brain, affords the readiest cause of the disease. Like epidemic meningitis, poliomyelitis appears in a frank and in an abortive or ambulatory form, can be transported by active infected carriers, as well as by healthy passive carriers of the specific microorganism of virus, and fortunately is limited in its extension by a high natural indisposition or insusceptibility to infection existing among persons of all ages.

4. **Relation of Gastric Secretion to Rheumatoid Arthritis.**—A. S. Woodwark and L. M. Wallis report the results of their study of ten typical cases of chronic rheumatoid arthritis. Ewald's test-meal, consisting of a piece of dry toast with one pint of weak tea without either sugar or milk, was given fasting, and the stomach contents were removed by a Señorans evacuator one hour later. In all of the cases the amount of free hydrochloric acid and the digestive properties were markedly below normal, and in some cases almost entirely absent. In the absence of signs and symptoms malignant disease of the stomach could be excluded. Apart from the circumstance that in many cases an obvious septic focus—*e.g.* carious teeth—is at hand, the identification of the source of sepsis does not appear to be essential, since opportunities for the introduction of pyogenic microorganisms into the body are manifold and insidious. The absence of hydrochloric acid also explains the frequency with which dyspepsia is encountered in cases of rheumatoid arthritis. The lines of treatment adopted as a natural sequence were to remedy the defect in the gastric secretion, and although these have been employed only for a short period of time, the results have so far been encouraging.

5. **Wire Sutures.**—E. W. Hey Groves for some years past has been much impressed with the superior advantages of iron wire over other metal wires in more common use for surgical operations. As regards silver, the material which is probably more widely used than any other, it has long been known that fractures of the patella united by silver wire are apt to re-fracture. This is often due to the fact that the sutures only grasp a thin shell of cancellous bone, but it has also resulted from the fracture of the wire. But the fact that silver wire not only occasionally, but generally, becomes disintegrated in the tissues has been conclusively proved by recent *x*-ray photographs of the late results of the filigree operation for hernia. There is only one other kind of wire that is at all commonly used in surgery besides silver—viz., aluminum bronze. The author has found this easy and satisfactory to work with, but he has also been struck by the fact in animal experiments that the tissues in the neighborhood of the wire are always discolored by a green deposit which is no doubt a copper compound, and healing is always delayed or altogether absent in these green tissues.

6. A Case of Ulcerative Endocarditis. A. Houlgrave.
7. A Case of Abnormal Pulse Rhythm. W. Johnstone.

1. **Surgical Dyspepsias.**—A. J. Walton discusses the variations of symptoms and physical signs occurring in gastric ulcer, early gastric carcinoma, duodenal ulcer, gallstones, and some cases of appendicitis. Pain is the most important although not always the first symptom, but it is the pain that causes the patient to seek advice. Variations in the appetite in these lesions are common and seem to depend largely upon the changes in the secretion of hydrochloric acid. Vomiting is extremely variable and apart from the presence of blood is of no aid in arriving at a differential diagnosis. The indications for operative treatment are as follows: (1) Any case in which the symptoms are such that one of the above lesions can be diagnosed with tolerable certainty. (2) Any case commencing after the age of 35, which is not markedly relieved by a few weeks' adequate medical treatment. (3) Any case in which the symptoms have occurred after previous attacks relieved by medical treatment, especially if the symptoms have changed from those typical of a chronic gastric ulcer. (4) Any case in which the stomach shows definite evidence of distention, whether the symptoms are those of ulcer or carcinoma. (5) Any case in which a tumor is present suggesting any of the above conditions. (6) Any case with repeated hemorrhages.

Congenital Deformity of the Forearm.—H. G. W. Dawson calls attention to a condition which has apparently not been described in the textbooks. This condition is one of congenital union of the upper end of the radius with the ulna, resulting in a fixation of the forearm in a position of complete pronation and limitation to the usefulness of the arms and hands. The author's case was that of a lady aged 35, in whom the condition was bilateral. A younger brother was also the subject of the same deformity.

Miner's Nystagmus.—F. J. Browne and J. R. Mackenzie point out the following etiological factors in this condition: (1) *Inadequate Light.*—That this is an important cause of miner's nystagnus is conclusively proved by the fact that 99 per cent. of the author's cases had been using the locklamp for a number of years. (2) *Errors of Refraction.*—These occurred in 90 per cent. of the cases. It is interesting to note that a large number of the cases of hypermetropia were those of comparatively young men who had worked only a few years at coal-cutting. (3) *Straining of the Extrinsic Muscles of the Eyeball.*—This is the result of the two foregoing factors. In all the cases the workman had his eyes fixed in a staring, strained

position for long periods, either downwards and laterally, as in narrow seams, or upwards, as in wide seams. (4) *Neurotic Temperament.*—The inability, on the part of a very large number of men with nystagmus, to concentrate their physical or mental powers in any particular line of action suggests that such instability is probably much more the cause than the effect of nystagmus. The severe headaches and aching eyes of which these men complain are accounted for by errors of refraction and straining of the eyes; the vertigo, by incoordination of the ocular muscles; and the conjunctivitis and photophobia, by the sudden frequent change from darkness into dazzling light.

Berliner klinische Wochenschrift.

September 23, 1912.

Extirpation of the Spleen in the Normal Man.—Noguchi refers to the results of extirpation of the spleen in general, but owing to the fact that this is done in various pathologic states the finds show corresponding differences. Hence data must be compiled only from cases of extirpation in the healthy. The case described by the author, however, was not in a perfectly healthy subject, such as might have happened in a traumatic case but in a man with a large lipoma, to which the spleen was hopelessly adherent. The spleen was, however, intact in every way. The patient was subjected to an extended study and the author sums up as follows: The extirpation of the normal spleen in a normal subject gives rise to no disturbance of the economy. The subject lives on for many years and shows no abnormalities. The only significant blood change is a diminution of the polynuclear neutrophiles. During the first year this is offset by increase in the lymphocytes and later in the eosinophiles. In the course of a few years this shortage in the neutrophiles disappears, perhaps because the bone marrow is able to supply them. Five or six years are required before the fluctuations in the neutrophiles and eosinophiles cease. Only a portion of the former are manufactured in the spleen. In affections of the latter organ, such as Banti's disease and malaria, the shortage in neutrophiles is also made up by other organs, in such manner that it is not apparent. Splenectomy appears to throw no light on other functions of the organ. In general the results of splenectomy are slight and transitory.

Perforation of a Postoperative Peptic Ulcer of the Duodenum into the Transverse Colon.—Pinner reports a case of this type, and states that it makes the tenth on record. In all of these cases the conditions were the same, viz.: the perforation followed a retrocolic gastroenterostomy. It is evidently immaterial whether the operation was done on the anterior or posterior wall of the stomach: whether or not a Murphy button or some other resource was used. The jejunal ulcer may occur after any method. The author gives a digression on the causation of peptic ulcer in the jejunum. The general assumption is that a hyperacid gastric juice is at fault, and this is no doubt the chief factor. But not in every case do we find evidences of hyperchlorhydria, and similar ulcers may occur in the normal jejunum in which only alkaline secretions are present. In such cases we have to fall back on local injuries, embolism, arteriosclerosis, etc., as possible factors. Once these ulcers form perforation into the colon is readily intelligible. Diagnosis should not be difficult in theory. After the gastroenterostomy, the entrance of colonic products into the stomach and vomited matter, as well as dysenteriform symptoms make the case a plain one. In practice, however, these symptoms may be quite lacking. In certain cases pains have constituted the sole symptom. The subject of prevention is bound up with that of diet, but authorities are not agreed as to what this should be. Naturally the continued presence of the original disease which led to the operation may demand constant attention. The only treatment proper is naturally a second operation.

The Graves' Syndrome in Pulmonary Tuberculosis.—Von Brandenstein, a woman practitioner, deals with this subject exhaustively. Certain symptoms of pretuberculosis, such as tachycardia might suggest a Graves' element. This, however, is not the contention, the latter being that actual Graves' is more common in consumptives than in patients as a whole. In a tuberculosis sanatorium it was learned recently that about 16 per cent. had Graves' disease, about one-half in a severe form. The present author thereupon investigated some tuberculous material for evidences of this association, and if we include the abortive types she found Graves' disease in nearly 30 per cent. of the women patients and 20 per cent. of the men. All the insignia of the syndrome, including blood pictures were taken into account.

Münchener medizinische Wochenschrift.

September 24 and October 1, 1912.

Chorea Luetica.—Flatau refers to the infrequency of this condition. Since true chorea is an affection of childhood, syphilitic chorea should in theory occur rather in the inherited cases. But choreic affections occur at any age and some of these might well have a syphilitic element. Naturally the biological tests will throw new light on this subject. The author's personal case is of special interest as showing the existence of a familiar type of chorea. Four children of a syphilitic father had been affected with this disease at some time. All recovered after a relatively short illness. The author is unable to find any parallel experiences in literature. Recently, however, he has seen a case himself in which with no actual history of syphilis a positive Wassermann reaction was obtained. In this case there were a history and evidences of some intracranial affection in infancy. Recovery under salvarsan appeared to clinch the diagnosis. No doubt a Wassermann test of all cases of chorea and choreiform movements would reveal a certain element of syphilis.

Recovery after Pylephlebitic Abscesses in the Liver.—Franke relates a case of this character which is a rarity in the temperate zones. The primary lesion was an appendicitis which was severe enough for operation. Later there were repeated chills and a painful hepatic tumor. Laparotomy was performed and an abscess of the right lobe was opened. The urine had contained an abundance of urobilin. There was little or no improvement after evacuation of the abscess, which pointed to the presence of others in the same organ. This was punctured without relief. Chills, urobilinuria, etc., still kept on, and the patient's condition showed the presence of a severe constitutional malady. After long delay another laparotomy was done, whereupon the presence of a second good-sized abscess was readily established in the left lobe. This was evacuated and patient at once improved. There could be no doubt that a pylephlebitis had determined the suppuration in the liver.

Bullet in the Fourth Ventricle for Years.—Jaeger describes a case which is perhaps unique. Patient was a man aged 27, who had attempted suicide with a revolver. The picture which had resulted from the injury was left spastic hemiparesis with ataxia, so-called "blickparalysis," "nystagmus and numerous other disturbances of the eyes, bulbar speech disturbance, compulsory laughter, and attacks of clonus in the flexors of the paretic left arm. Some of these symptoms were doubtless due to the lesions made by the bullet in reaching the ventricle. The general location of the foreign body was readily shown by radiography. Later the patient was subjected to trephining as a hoped-for life-saving resource; for owing to the proximity of the important centers in the medulla there was danger that any destructive process might involve them. Certain disturbances in respiration and deglutition, while slight, caused some apprehension from this viewpoint. The

trephine intervention undertaken by way of the occiput in the hope of extracting the ball not only failed but was followed by fatal collapse. The bullet was found high up in the ventricle in the middle line. The wound of the encephalon had resulted in areas of softening and the formation of cicatricial tissue.

Hypokinetic and Dyskinetic Constipation.—Schwarz, an assistant of Professor von Noorden, has studied constipation extensively by means of radiography. Pictures of fecal distribution in the healthy subject, taken 24 hours after a test meal, show, as is well known, one large mass in the vicinity of the sigmoid, and numerous small discrete masses scattered through the length of the colon. The large mass is known as the *globus pelvicus*. If pictures of constipated subjects are taken, they show the existence of two principal types. In the first we note as late as 48 hours after the test meal no typical globus pelvicus, the feces being still distributed along the colon which latter is often unnaturally long and convoluted. In the other form we see after 48 hours a globus pelvicus, but the colonic feces appear to have been forced backward toward the cecum. The socalled fecal column is therefore separated into two widely separated masses. This corresponds clinically to "constipation of the ascending colon." In the first form, by contrast, the fecal column is continuous, occupying a large portion of the colon uniformly, there being no massing of fecal matter at either extremity. We see here the same old contrast which has obtained in former years as atonic and spastic constipation. The terms employed by the author—hypokinetic and dyskinetic—represent the same conditions. In the former case the bowels may appear to move regularly but the evacuations are only fragmentary, as becomes atony. In the other type there is spasmodic retention.

Tropical Diseases and the Cinematograph.—Olpp states the cinematograph was first used in connection with medicine in the last decade of the nineteenth century, and its history naturally occupies three sharply differentiated epochs. In 1897 began the study of abnormal gaits and movements in general. The movements of the exposed organs of living animals—of the heart and lungs, stomach and intestines—were illustrated. The proper movements of the larynx were also exhibited. The second stage began with the use of an improved technique which rendered visible movements naturally hidden from the eye, notably those of the heart, diaphragm, and digestive apparatus. The third stage necessarily began with the introduction of the microscope. The latter is of especial interest for tropical medicine. In 1908 Reicher first showed the movements of the blood corpuscles, and one year later Comandon made beautiful pictures of phagocytosis in connection with trypanosomes. The author, who studied with Comandon, has carried out his technique in the attempted demonstration of the parasitology of four diseases to which dwellers in the tropics are particularly exposed, viz., Malta fever, the plague, leprosy, and cholera, in all of which the bacterial origin has been demonstrated beyond doubt. But of these four but one bacterium shows active proper movements, the cholera vibrio. A culture of the latter shows in the cinematograph all the characteristic movements. Dutton's spirochete, the cause of African relapsing fever, may be shown in the act of penetrating an erythrocyte. The ticks, which by acting as hosts for bacteria disseminate much disease, may be shown in the act of bloodsucking. It is in depicting the daily life of these insect hosts that the cinematograph may be made of great educational value. The ameba is naturally, as its name implies (changing), an admirable subject for pictures, as is also the blood parasite schistosomum. The larvæ of sensibly large parasites are also among the objects which lend themselves readily to representation in motion pictures.

Deutsche medizinische Wochenschrift.

September 26, 1912.

Noises in the Ears.—Wittmaack considers these very fully. Naturally the chief attention is given to cases in which examination of the ears gives negative results, the hearing being unimpaired. The possibility always remains that some insidious organic affection is nevertheless present in an initial stage. An important division is into rhythmic and arrhythmic sounds, the former being chiefly pulsatile in character. A periodic rhythm may be of cardiac or cardiorespiratory origin, but there is also a rhythm, much less steady, which proceeds from the entotic muscles or perhaps from extrinsic neighboring muscles. Thus habitual swallowing could be transmitted to the ear as a sound. Whatever the immediate causes of these sounds they almost all repose on a neuropathic substratum, and subjective ear noises are almost *prima facie* evidences of neurasthenia. Hysteria also furnishes a predisposition. There may be vascular pulsating sounds which are not neurogenic, and in such a case a small aneurysm could be responsible. The author finds that sounds of vascular type occurring in a neurasthenic are especially hard to combat. He has also found that the presence of actual noises in the environment diminishes the patient's perceptions, and that actual rhythmic noises, such as those of a clock ticking, divert his attention. The tendency of these neurasthenics to seek noiseless places is deprecated. The more silent the environment the more the subject notices these sounds of intrinsic origin. The author praises the old empirical remedy hydrobromic acid, and the bromides, and valerians in general. Nearly every local and systemic method of treatment, the author says, appears to have been tested in the attempt to quiet, or at least secure relief from these noises.

Hemoglobinophile Bacteria.—Scheller, writing from Pfeiffer's laboratory, touches upon the controversies in respect to influenza bacilli and pseudo-influenza bacilli. The Koch-Weeks bacillus belongs to the same group as the *B. influenzæ* but differs from the latter. Other closely related germs are the *B. pertussis* and several forms pathogenic to animals. Everything goes to show that the *B. influenzæ* is not the sole germ which causes the grippe, although a difference of opinion obtains as to whether or not the atypical cases represent mixed infection in which the *B. influenzæ* coöperates with one of the other microörganisms. Pfeiffer himself has seen grippe in which the germ which goes by his name was surely absent. The general impression at present is that there is a large group of bacteria characterized by hemoglobinophilia which have a wide range of pathogenicity. Among the diseases attributed to members of this group are such opposites as cholera nostras and meningitis. One can understand why this type of bacterium may show such a range of pathogenicity. The hemophile bacteria which are believed to be members of a common group, says Scheller, may include Pfeiffer's influenza bacillus, the Bordet-Gengou whooping cough bacillus, Cohen's meningitis bacillus, Beck's *Bacillus pneumonicus*, the Koch-Weeks conjunctivitis bacillus, etc., etc.

Action of Mercurials in Spirochete Diseases.—Abelin has shown that the toxicity of mercurial salts is dependent largely on their chemical constitution. Through the introduction of certain atomic groups (sulpho-group, sulphamino group) the toxicity of Hg is depressed. The most toxic combinations are those in which the Hg can be transferred to the ionic state. The aromatic metallic-organic combinations in which the ionic state is not readily assumed are less toxic than the former which comprise the bichloride, calomel and the succinimide. Abelin says that experience has shown that these nontoxic salts are not inferior as spirocheticides.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

By the Insurance Editor.

THE EXAMINATION OF WOMEN.

Medical examiners are apt to experience a feeling of timidity when the applicant happens to be a woman and to apprehend that they will incur her displeasure if they ply all the pointed and direct questions which appear in the examination blank, or if they insist on a complete examination. If the same woman were to come to one of these examiners as a private patient, even though an utter stranger, he would not hesitate to put her through a process of rigid catechism in regard to her strictly personal affairs and most intimate relations in so far as they would have any connection with the case, and furthermore, to request her to submit to a physical examination perhaps even more searching than that required when she is applying for life insurance. Allowing for the difference in the circumstances, there is no good reason why a physician should not carry out his task with equal thoroughness in both cases. It may be depended upon that a woman will feel ill at ease and uncomfortable if the examiner gives any indication by his demeanor that he has a delicate and unpleasant mission to perform and that he fears he will wound her susceptibilities. If, on the other hand, he goes about his work in an easy, polite and matter-of-fact way, courteously but with veiled firmness, insisting on the fulfillment of all the requirements of the company, he will not create any occasion for embarrassment or annoyance. Good judgment in forming and putting the questions is also necessary; as, for instance, it might be unwise to bluntly ask a young, refined, delicate-minded, and unmarried woman if she is pregnant. Yet this query appears in the blank and must be answered in every case, whether the woman is married or single, and the information may be easily obtained by securing from her a full history of her menstruations and the date of the last one. The same line of questions will bring out the fact as to whether or not she has ever borne children. When answers brought out in this way have been recorded, however, the applicant should be asked to read that part of the report carefully and to state if they are correct. Modesty, then, may and should be thoughtfully regarded, but this consideration should never be allowed to interfere with thorough work.

It is especially important to observe the following admonitions:

1. The examiners are depended upon to make both the inquiries into the past history and the physical examination with scrupulous care and not to take anything for granted. They will, indeed, soon find that close and persistent questioning is often necessary in order to elicit a full, definite history, owing to the failure of the average woman to realize that she becomes party to a legal contract when she signs an application for insurance or to grasp the strict business principles involved in the making of a contract, and also to her natural tendency to avoid the subject of the diseases and ailments peculiar to her sex.

2. The examiner should adhere strictly to the rule which forbids the presence of a third person (even the husband) while he asks the questions on the examination blank. The object of this restriction is to secure free answers without any restraint or influence. During the physical examination, however, it is proper to have a friend or relative present if the applicant desires it.

3. The applicant should be previously instructed, when possible, to arrange her clothing in such a way as to insure ease, facility, and thoroughness in the examination. A loose gown of some light weight material will answer the purpose admirably. At least, if she has not done this, she should be requested to remove her corsets and other heavy apparel which would interfere with the inspection of the chest and abdomen.

4. The chest measurements should be taken horizontally immediately below the axilla, avoiding the mammæ. The abdominal measurement should be taken at the waist line, as well as at the level of the umbilicus, as requested in the examination blank, care being taken not to include the crests of the ilia. If the abdomen be large below this line, the examiner should ascertain whether it is merely adipose and pendulous, or whether there is a possibility of tumor or pregnancy. The proper methods of measuring are fully discussed in a previous section on "Height, Weight, and Measurements."

5. The urine must be passed at the time of the examination. If this is not possible the examiner must obtain it later himself; in no case should he permit it to be sent or brought to him. The examiner can easily obtain the urine under circumstances which assure him it was voided by the applicant, by arranging to have it passed in his own office or even at her residence while he temporarily adjourns to the next room. The urine should be warm when presented to him and in the container which he gave her for that purpose.

6. A pregnant woman may be examined according to the rules of some companies, usually provided she has previously been through a normal labor.

7. The mortality among insured women is so high when any element of speculation enters the case that the home office staff will carefully criticise an application made by a wife for the benefit of her husband, or by an elderly woman for the benefit of adult children. In these cases, therefore, the examiner should be especially cautious and report confidentially to the medical department any suspicious circumstances connected with the case.

8. The mortality among young unmarried women who are insured is high, and is largely due to tuberculosis. For this reason the examiner is called upon to be very thorough in his examination of the lungs of these applicants.

Albuminuria.—L. Huismans says that mere examination for albumin is no longer sufficient for the diagnosis of nephritis, but a microscopical examination of the sediment should likewise be done. Such examinations have taught us to differentiate acute inflammations of the kidneys, in which the urine is of high specific gravity, is small in quantity, contains much albumin and many and various casts, from more chronic types of the disease with urine of low specific gravity, abundant in quantity, containing but little albumin, and few hyaline or granular casts. It must be remembered, too, that albumin may be absent for weeks in cases of granular kidney and, on the other hand, cases have been published which in life gave signs and symptoms of nephritis, yet at autopsy showed normal kidneys. Moreover, various toxic states and mechanical causes may be responsible for the appearance of

albumin in the urine, and these must be correctly judged in reference to the question of prognosis in individual cases.

Frequently a slight opalescence produced in the urine on boiling is interpreted to mean the presence of albumin, yet it is quite possible that other precipitations may explain this appearance, and further tests, not often performed in the routine of insurance examinations, are necessary. Huismans tells of an applicant who was accepted at much higher rates than his age demanded, some fifteen years ago, because of the "slight trace of albumin" found in the urine. Fifteen years later this patient was examined by the author and no albumin was found, but a somewhat deceptive precipitation of crystals instead. Moreover, traces of albumin have been found in quite healthy persons after some unusual circumstances, *e.g.* after a prolonged march in soldiers, soon after very cold baths, during menstrual periods in women, after sexual excesses, etc. Orthostatic albuminuria, too, is not a very rare occurrence, and its significance not fully understood. Such persons should be insured, though a higher rate may be advisable.

Huismans tells of another patient in whose urine albumin was always found by another physician, while Huismans could discover none. Finally, he learned that the other physician happened to have samples of urine passed by the patient after fairly long bicycle rides, and the physical exertion may have accounted for the appearance of albumin. Of course, the appearance of albumin was somewhat abnormal, but Huismans' view of the case was, of course, less grave than the other doctor's. Huismans warns, too, against using very delicate reagents, such as Spiegel's, for most normal urines will show very faint traces of albumin with such reagents. The simple test by boiling and addition of nitric acid is probably the most dependable, for this is not very delicate and does away almost completely with the possibility of mistaking phosphates for albumin. The use of Esbach's reagent is somewhat dangerous, unless great care is used in examining the sediment. Crystals made up of picric acid of the reagent and certain elements of the urine which are deposited at the bottom of the albuminometer should not be mistaken for a precipitate of albumin.

If a patient in whom albumin has been found appears again for examination, other symptoms should be looked for to judge the significance of the albuminuria. The heart must be examined for hypertrophy, the second aortic sound for accentuation, and blood pressure should be carefully measured. Great importance should be attached to increase of blood pressure; if ten years or more after albumin has been found in the urine the blood pressure of a patient is not found increased, the interpretation of the urinary findings may be much less grave than otherwise.—*Blätter für Vertrauensärzte der Lebensversicherung,* Volume III, No. 1.

Life Insurance and Carious Teeth.—Nodine continues his remarks in proof of the intimate relation between health and a healthy mouth, disease and carious teeth, in urging that a dental examination should be made a part of the medical examination for life insurance. He says that rheumatic fever is an acute or attenuated general infection accompanied by a toxemia, with a variety of local manifestations, principally arthritis and carditis. He thinks that there is no doubt that the disease is caused by a microorganism, and that it is most probable that the mouth is its portal of entry into the system. The relation of the tonsils to rheumatism has been well proved, and these are most probably infected from carious teeth, foci of pyorrhea, etc. In addition such pathological conditions of the teeth allow other infective organisms to reach the organism and break down its normal resistance to such infections. Faulty teeth, too, lead to impaction of food particles in the mouth, and their decay, and interfere with the proper preparation of food for digestion in the stomach and intestines.

He thinks that infection may be the cause or one of the causes of diabetes and such infection could easily take place from a septic mouth. In any case, the resistance of the organism to infection is very much diminished in the course of a diabetes, and the existence of a septic mouth makes the danger of infection very actual in such cases.—*Oral Hygiene,* Vol. II, No. 7.

Relationship Between Life, Accident, and Health Insurance from a Medical Standpoint.—In the opinion of David H. Keller of Chicago the doctor who has to do with the consideration and disposition of applications and indemnity claims in the accident and health insurance field has always had a profound respect for the medical director of the life insurance company. This respect, however, is not always reciprocal, and Dr. Keller has found that the medical director of the life insurance company in his attitude toward the medical director of the accident and health insurance company, has been wont to assume a position of condescension. Such a position is unwarranted seeing that the matter of passing upon applications for life insurance is like taking candy from children, when compared to the consideration of applications and claims under accident and health policies. According to the writer the medical examiner for the accident and health insurance company must be all that the medical examiner for the life insurance company is, and also a Sherlock Holmes, and a "strong arm" man to boot.

There are few good accident and health insurance examiners who are not also good life insurance examiners, but there are many excellent life insurance examiners who are worthless as examiners of claimants under accident and health policies. This statement is no reflection on the latter. He is only a scientist. The successful medical examiner for accident and health insurance is an artist who has acquired science. Again, unlike the former the latter must count his very talents as a liability, if he employ them. It is not often that the individual whose application for life insurance is rejected holds a grudge against the examiner who reports his impairments, but woe to the accident and health insurance examiner when he accomplishes aught to reduce the amount of indemnity to which a claimant believes or pretends to believe himself entitled. Every rejected claim makes an enemy for the casualty company's medical officer. As private practitioners we have all known, Keller says, the sense of resentment which obtains when our patient is catechized and scrutinized by "the insurance company's doctor," and he says the accident examiner should not be unmindful of the fact that the local medical examiner for the casualty company is likely to make some doctor "sore" every time he examines a client, and that he deserves a lot of credit while taking the chance.—*Proceedings of the Second Mid-Year Meeting of the Medical Section of the American Life Convention.*

Book Reviews.

The Practical Medicine Series, Comprising ten volumes on the year's progress in medicine and surgery. Under the general editorial charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School, and Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School.

Volume I—General Medicine. Edited by Frank Billings, M.S., M.D., Head of the Medical Department and Dean of the Faculty of the Rush Medical College, Chicago, and J. H. Salisbury, A.M., M.D., Professor of Medicine, Chicago Clinical School. Series 1912. $1.50. Chicago: The Year-Book, Publishers.

Both specialists and general practitioners desire to be well informed regarding all advances in medicine, but find the mass of literature far too voluminous to admit of even partial reading. Such a volume as this, with its brief reviews of the year's literature, is therefore most welcome.

Volume II—General Surgery. Edited by John B. Murphy, A.M., M.D., LL.D., Professor of Surgery in the Northwestern University; Attending Surgeon and Chief of Staff of Mercy Hospital, Wesley Hospital, St. Joseph's Hospital, and Columbus Hospital; Consulting Surgeon to Cook County Hospital and Alexian Brothers Hospital, Chicago, Illinois. Series 1912. $2.00. Chicago: The Year-Book Publishers.

Surgical literature is being constantly enriched by many interesting and important papers on the newer methods of diagnosis and treatment and on rare surgical condition. This fact is clearly illustrated in this volume, which offers in concise form all such valuable material.

Volume III—The Eye, Ear, Nose and Throat. Edited by Casey A. Wood, C.M., M.D., D.C.L.; Albert H. Andrews, M.D., and Gustavus P. Head, M.D. Series 1912. $1.25. Chicago: The Year-Book, Publishers.

This book reviews briefly the literature of 1911, dealing with eye, ear, nose, and throat diseases, and discusses all the advances made in these specialties. It should prove useful to the busy practitioner.

The Life and Work of William Pryor Letchworth, Student and Minister of Public Benevolence. By J. N. Larned, Author of "A Study of Greatness in Men"; "Books, Culture, and Character," "Seventy Centuries of the Life of Mankind." Editor of "History for Ready Reference, etc." Price $2 net. Boston and New York: Houghton, Mifflin Company, 1912.

The record of a life devoted to the service of humanity is of general interest. The life of this philanthropist has also, for physicians, a special significance. His great work for the insane and epileptic and for the feeble-minded in New York State brought him into contact with medical men and medical thought, and his philanthropy contributed to the practical achievement of certain reformatory measures which are based on practical and scientific principles. Mr. Letchworth was a member of the State Board of Charities from 1873 to 1896. His activity in three special fields was noteworthy: First, the improvement of the homeless, wayward, and delinquent child; second, reforms in the care and custody of the insane and epileptic; and third, the preservation and maintenance of natural scenic and historic sites. During his service as State Charity Commissioner children and insane were rescued from the county poor houses; industrial schools were evolved from the old prison reformatories; colonies were created for the proper hygienic treatment of the epileptic; and the beautiful Letchworth estate of a thousand acres, called "Glen Iris," purchased to preserve the three falls of the Genesee River, was conveyed to the State of New York to be forever maintained as a public park. The writings and publications of this public-spirited man number over sixty-five. "The Insane in Foreign Countries" and "Care and Treatment of Epileptics" are among the most important. "Letchworth Village," a recently created establishment on the colony plan, for epileptic and feeble-minded, was named in Mr. Letchworth's honor. The biography is evidently authoritative, and its style entertaining. There are sixteen illustrations.

Sexual Impotence. By Victor G. Vecki, M.D., Consulting Genito-Urinary Surgeon to the Mount Zion Hospital, San Francisco. Fourth Edition, Enlarged. Philadelphia and London: W. B. Saunders Company, 1912.

This volume contains a description of the anatomy of the male genital organs, the physiology of the sexual act, a discussion of the subject of internal secretion, the different forms of impotence and their diagnosis and treatment. In discussing the subject of treatment the author reviews the various methods from time to time employed and relates his experience with them, giving special attention to the newer methods of suspension and hypnotic suggestion and entering a protest against urological atrocities committed on the complicated and delicate structures of the deep urethra. This part of the work will be of interest to the urologist. The author prides himself in having laid bare the truth and having plunged to the very bottom "to see what the gods have covered with darkness and horror." He seems to have found continence only in the chimera of the idealist, and while he warns against the responsibility of advising so serious a remedy as marriage for impotence he does not feel the same qualms in prescribing an illicit intercourse where this holds out a promise of helping the patient. The moralist will take issue with him on questions of ethics and will feel that while he may have discovered the whole truth as it is at the bottom he has missed some higher up which would be more palatable and more in accord with progressive teaching and sex hygiene.

Motive-Force and Motivation-Tracks. A Research in Will Psychology. By E. Boyd Barrett, S.J., Ph.D., Superior Institute, Louvain. Honors Graduate, National University, Ireland. Price, 7s. 6d. net. London, New York, Bombay and Calcutta: Longmans, Green & Co., 1911.

This is a distinctly technical thesis based largely upon experimental researches carried on for two years in the Psychological Laboratory of the Superior Institute of Philosophy at Louvain University. The standpoint adopted in the book is therefore strictly empirical and experimental. The introspective method of the Würzburg school is followed, and the terminology of modern psychology is employed. The book is especially valuable to those engaged in the study of the will and of character. The general reader, however, will find in it much of real interest, even if he is unable to follow intelligently the technical side. After an introduction describing the backward state of a will psychology, and the pressing need of one, the author devotes himself, chiefly by experimental researches, to the analysis of various phases of the choice-process. The plan of the book is the discussion of motives, motive-force and its measurement, motivation-tracks, the evolution of motivation, automatism, hesitation, hedonism, the relativity of values, and the psychology of character. The aim of education at the present day tends, as the author states, toward a training of the will and of the intellect, rather than to a mere burdening of the memory. A science of man has not yet been produced. The problem of character-formation and will-education, therefore, presents innumerable difficulties. It is truly calculated to gain a measure of practical assistance, however, from this research which is a step in the direction of an efficient psychology of the will.

Text-book for Nurses. Anatomy, Physiology, Surgery and Medicine. By E. W. Hey Groves, M.S., F.R.C.S., Assistant Surgeon, Bristol General Hospital; Clinical Lecturer, University of Bristol, and J. M. Fortescue-Brickdale, M.A., M.D., Assistant Physician, Bristol Royal Infirmary, Clinical Lecturer, University of Bristol. London: Henry Frowde, Oxford University Press, and Hodder & Stoughton, 1912.

A perusal of this volume, without reference to the title page, would lead one to pronounce this book an admirable résumé of the essentials of anatomy, physiology, surgery, and practice. As such it can be most unreservedly recommended to the junior practitioner or senior student. Unfortunately the title page announces that the work is intended as a text-book for nurses. So far as the quality of the mental pabulum here provided is concerned the nurses could have nothing better. But if, in addition to the scientific knowledge contained in this work, they are supposed to learn and to practice what may be called practical nursing, we wonder when and how they will acquire this extra knowledge. This volume contains nothing on nursing, materia medica, dosage, solutions, and many other subjects most important for nurses. With this book as a basis the nurse will be in a fair position to see that the doctor in (nominal) charge of the case does his duty; but the patient would probably fare infinitely better at the hands of one who had less theoretical information and more practical knowledge of the details of nursing. We are well aware that there are two opinions on the question of the necessity or desirability of the nurse acquiring the education of a medical student; and extremists in this matter will pronounce the present volume either ideal or useless.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 4, 1912.

DR. LUCIUS W. HOTCHKISS IN THE CHAIR.

Case of Partial Resection of the Stomach for Carcinoma.—Dr. HERMANN FISCHER presented this patient, a man 30 years of age. The patient gave a history of chancre about ten years ago which was treated with inunctions of mercury. His present trouble dated back about one and one-half years previous to his admission to the hospital. For ten months previous to his admission he had had gastric distention and vomiting which occurred five or six hours after eating. His appetite was fairly good. He was emaciated and had a large round tumor in the epigastrium. The gastric secretion showed free hydrochloric acid, but no blood and no lactic acid and there was no coffee ground vomiting. A few salvarsan injections were given and mercury subcutaneously, but without effect. At operation a carcinoma was found at the pyloric end of the stomach and an hour-glass stomach. The mass was fairly movable and a resection was done after the Kraske method. Some of the pancreatic tissue was also cut away. A small fistula developed from the seventh to the ninth day after the operation, but this soon closed. It was now nine months since the operation was performed and the patient was in good health.

Appendectomy, Ureterolithotomy and Herniotomy.—Dr. W. H. LUCKETT presented this case. The patient was a man 46 years of age, who had had a right inguinal hernia of five years' standing and pain for two years. Dr. Luckett thought he could differentiate pains referable to the appendix and to a right ureteral calculus. Both the appendectomy and the lithotomy were done through the same incision. The appendix was found chronically inflamed, and after its removal the peritoneum was closed and the calculus was removed retroperitoneally. The stone was small. The same incision was then continued down over the hernia. The entire operation was completed in less than forty minutes and the patient made a good recovery.

Two Cases of Colles' Fracture.—Dr. GEORGE H. HOUGHTON of Albany presented these cases.

CASE I.—This case was of particular interest because the patient, when a boy 12 years of age, had fractured his left wrist and there was apparently arrested growth. The right wrist had been broken in the same way and it was interesting to note the different results obtained by the different ways of treating the fractures. Dr. Houghton exhibited an *x*-ray picture of the injury, showing several lines of fracture; the styloid process and the end of the ulna were broken and there was distinct crepitus everywhere in the wrist. In dressing this fracture he used the splints which he had devised. Perfect function had been secured and the arm was as strong as ever.

CASE II.—This patient had a very bad arm. Dr. Houghton did not see him until the third day after the fracture occurred when the arm was much swollen. Both bones were broken and the lower segment was driven inward. The *x*-ray exhibited showed both bones broken and much spreading on both sides. In this case also he had secured perfect results. Both men were carpenters and could drive nails into the ceiling, a task few could accomplish after having sustained a Colles' fracture.

A New Principle in Esophagoscopy and Gastroscopy.—Dr. RICHARD LEWISOHN presented this communication which contained a description of his new esophagoscope and the method of using it, and an outline of the work that he had done on a gastroscope which was not yet perfected. After pointing out the disproportion between the work done in cystoscopy and that done in esophagoscopy he said that this disproportion could only be explained by the fact that as yet it had been impossible to construct an esophagoscope that could be used with the same safety and reliability as the cystoscope. It was not that there was no demand for such an instrument. The great number of instruments hitherto constructed fell into two distinct groups: (1) straight tubes, which were introduced with the head in hyperextension; and (2) jointed tubes, which were only straightened after their introduction into the esophagus. The straight tubes, in spite of their simplicity of construction, were very unpopular because their introduction was associated with the greatest discomfort and even danger to the patient. Instruments of this character did not take into consideration the normal rectangular formation existing between the oral cavity and the esophagus which was only partially obliterated by hyperextension of the head. As for the dangers it was well known that their use had been followed by a large proportion of perforations of the esophagus which resulted fatally. The same danger existed with the jointed tube. On the basis of these observations Dr. Lewisohn concluded that a satisfactory esophagoscope must fulfill the three following main requirements: (1) The introduction must be possible in the normal position of the head. (2) The instrument must be so constructed that it actually passed into the longitudinal axis of the esophagus and not at an angle to this axis. (3) The esophagoscope should only be passed downward along the esophagus under guidance of the eye to avoid perforations. The instrument which Dr. Lewisohn had devised, based on these considerations, consisted of two portions which were joined together at almost a right angle; the horizontal portion which lay in the mouth of the patient during examination, and the vertical portion consisting of a telescope, composed of six separate tubes which might be pushed down into the esophagus as far as necessary. The horizontal portion consisted of two parts which could be separated by traction in a horizontal direction. These two parts each had a hemicylindrical canal which formed a tube. In this tube the spring which was necessary for the manipulation of the telescope rested. Thus the spring lay entirely outside of the main horizontal tube and did not disturb the passage of the light rays. The lamp of the illuminating apparatus was copied from one constructed by Fischer of Freiburg, but it gave a much more intense light. A very intense light was necessary because the rays were broken three times before they reached the eye of the observer. Directly under the lamp a condenser was placed which concentrated the rays. The rays then fell on a mirror which was movable on a horizontal axis. From this mirror they were thrown to a second mirror which lay at the junction of the horizontal and vertical portions of the instrument. This second mirror interrupted the rays in such a fashion that they fell directly downward in the telescope. The telescope was the essential novelty of this instrument, and consisted of six steel tubes, the walls of which were 0.3 millimeters thick, and which could be projected into the esophagus. The mechanism of these tubes was very complicated. At the lower end of the innermost tube was a metal ring which could be unscrewed and which opened the lumen of the esophagus when the telescope was pushed down. This ring also facilitated the downward passage of the telescope. Attached to the lower part of the upper tube were two metal guides which greatly facilitated the introduction of the instrument. The length of the telescope was thirty-three centimeters when opened. The diameter of the six tubes varied from twelve millimeters for the lowest tube to seventeen millimeters for the uppermost. It would be possible to add another tube with a diameter of eighteen millimeters which would add five centiners to the length of the telescope and make it possible to pass the instrument into the stomach. On account of the angular construction of this instrument it was necessary to devise an aspirator somewhat different from that ordinarily in use in the straight esophagoscope. He had succeeded in constructing such an instrument so that the aspiration of mucus was as easy and certain as with the straight tube. He demonstrated a forceps and said he hoped soon to be able to present one which could be used as successfully as that now used in the straight tube. In examining the patient with this instrument the method was as follows: The patient was placed on a chair, the head being supported by an assistant. The larynx was anesthetized with a 10 or 20 per cent solution of cocaine and then the introduction of the esophagoscope accomplished in two stages. The instrument was first "anchored" in the esophagus and then passed into the deeper parts of the esophagus. Although the anchoring of the instrument in the mouth of the esophagus was performed blindly, the second stage of the process was only undertaken under the guidance of the eye. It was essential that the lumen of the esophagus be always kept in the field of vision. The advantages of this right-angular telescope, as compared with the straight tube were very marked. It was immaterial whether the patient had an easily movable cervical spine or a full set of teeth or not. The head was not brought into any strained position. The finding of the entrance to the esophagus occurred here automatically and blindly. The opening of the telescope was

so simple because this instrument was the first that could be really pushed down into the longitudinal axis of the esophagus and not at an angle to the axis. In looking for an incipient cancer the telescope could be pushed down at least half a dozen times and the entire organ thoroughly inspected. While esophagoscopy would always be for the majority of patients a more disagreeable procedure than cystoscopy, there was no comparison in the disagreeableness caused by this new instrument to the extreme discomfort produced by the straight tube esophagoscope. Dr. Lewisohn then showed that there was need of such an instrument for the diagnosis of incipient carcinoma of the esophagus and that it was also of importance in differential diagnosis. He was convinced that esophageal disease was by no means infrequent, and that when their diagnostic methods had reached a greater degree of perfection it would be seen that the lesions of the esophagus were proportionately of common occurrence. The author then reported a number of cases in which, after other methods had failed, he had by means of this instrument been able to make a correct diagnosis. He then described his gastroscope to which he had applied the principles above expounded. The difficulties to be overcome in successful gastroscopy were greater than in esophagoscopy, as it was absolutely necessary for the inspection of a hollow viscus that the illuminating and optical apparatus could be brought easily to all portions of the wall of the organ and the anatomy and physiology of the stomach on the one hand and the relations existing between the esophagus, spinal column, and stomach on the other made this extremely difficult of accomplishment. The vertical position of the stomach also interfered with the free mobility of the optical apparatus. The repeated inflations which were necessary always brought different portions of the stomach into the visual field, thus making impossible a thorough inspection of that portion which might be of special interest. Dr. Lewisohn said that his efforts in the construction of this instrument had convinced him that they could and must develop gastroscopy which was as yet in its infant stage.

Dr. Willy Meyer said there could be no doubt but that this instrument meant a great step forward. Dr. Lewisohn deserved great credit for the effort and patience, to say nothing of the expense, incurred in making this improved instrument. Whoever had had a patient who could not bend his head back and had found it absolutely impossible to make an examination with the straight tube, if he but once saw Dr. Lewisohn work his instrument, must admit that it was a great step forward. Dr. Lewisohn was right in what he had said about the danger of the straight tube. Even the most careful men had made perforations. He had taken great pleasure in witnessing the ease with which Dr. Lewisohn made examinatoins with this new instrument. The instrument could be introduced in a few seconds and the patient could stand it comfortably for twenty-five or thirty minutes.

Dr. Henry H. Janeway said he was much interested in this new instrument and thought Dr. Lewisohn deserved a great deal of credit. Examinations of the stomach and esophagus should be made more frequently than had hitherto been possible. He said he could not discuss the new instrument, but that remarks made about the straight instrument showed that some of them were not familiar with it. He had used the straight instrument in making about one hundred examinations and a number of the patients, when questioned said they would be willing to take the examination again. There was everything in the way the straight tube was used. There was no excuse for using force Of course there was more discomfort where there was kyphosis, but here the examination might be made under an anesthetic. There was no excuse for making a perforation. Occasionally he failed to get a piece of tumor with the straight instrument, but, while he had been prejudiced against it he had been surprised with his own success in using it. One could see the vertical portion of the stomach and the cardia with the straight tube.

Dr. Wolff Freudenthal said he had used many of the best instruments and he preferred Bried's. There were more accidents after esophagoscopy than after bronchoscopy. He related one instance of sudden death after bronchoscopy. It was difficult to introduce the instrument in a certain percentage of cases with curvature of the spine, but he could overcome the difficulty in 99 per cent. of the cases.

Dr. William H. Stewart said he had recently heard a paper read by a Pittsburgh physician in which it had been pointed out that the introduction of an instrument would be greatly facilitated by placing the patient on the table and allowing the head to hang over the edge of the table.

Dr. Lucius W. Hotchkiss said he thought the instrumnt presented was an important advance and that the sectilon had been fortunate in having Dr. Lewisohn show them his work.

Dr. Lewisohn, in closing the discussion, said esophagoscopy was not popular and that it had never been popular. Some good experts could do a straight esophagoscopy, but they were very rare. The straight esophagoscope could be used by only a few and they certainly needed an instrument that could be used by a greater number with some feeling of security.

Reducing and Treating Colles' Fracture by Means of a New Device or a Metal Splint.—Dr. George H. Houghton of Albany read this paper which he illustrated by lantern slides. He said that it had been his endeavor to construct a splint along normal anatomical lines for fractured wrists and lower forearms that would come in contact, support, fit snugly, and produce equal pressure over or along injured parts, and that could be adjusted in such a manner that it could be comfortably worn by the patient and at the same time produce practically a normal result. In order to accomplish this he had first to secure a forearm, hand and wrist of full medium size as nearly anatomically perfect as possible; this was no easy matter, but having secured the specimen the next step was to place it in plaster-of-Paris. The position of the arm, wrist and hand in securing this plaster cast was all important. The wrist had to be flexed at least one-half of its normal capacity; the forearm had to be well flexed at the elbow and in a prone position. The elbow had to be raised to such a position that the humerus was at or near right angles to the body. The forearm had to be rotated well inward. He had chosen aluminum as the metal most suited for this purpose, as it was capable of being rendered aseptic, was light, strong and practically non-corrosive; it also had some spring to it and retained heat for a long time. The splint was divided into two equal parts and could be adjusted by means of lugs and screws so as to fit any arm. After determining the proper adjustment by fitting the splint to the uninjured arm, the patient was placed in a low stool beside a firm box or table. The arm was flexed at right angles, elbow elevated at right angles to the body, forearm rotated well inward, and the arm placed in the splint. Then the operator placed his thumbs firmly over the seat of fracture and forced the bone or bones into normal position. As a rule, one would sense a pronounced crepitus as the bones were forced into position. If the fracture could not be reduced in this manner recourse might be had to a lever action. A strip might be placed around the splint above the middle lug and a firm piece of felt placed over the seat of fracture and a normal adjustment secured by pressing the lever downward. After satisfying yourself that the impaction was broken up and the fractured parts properly adjusted, a piece of silence cloth was placed over the entire inner surface of the splint and fastened in position by means of stitching along the edge of the splint through the perforations. Then, with the aid of an assistant, the arm was adjusted to the splint and adhesive plaster placed over the hand. Extension and counter extension were obtained by having the assistant grasp the upper arm firmly with one hand and with the other force the splint in the opposite direction, while the adhesive plaster was applied to the upper end of the splint and across the fleshy part of the upper forearm. It was not necessary to use any great amount of force in making extension and counter extension, ten or twelve pounds pressure being sufficient. A firm piece of felt was then placed over the fracture and fastened with adhesive plaster, leaving the end of the ulna exposed; pressure over the lower end of the ulna caused the patient pain. By keeping the injured member elevated as much as possible the swelling should disappear almost entirely in three or four days. If the patient suffered pain after the first two or three days the fracture was not sufficiently reduced or the wrist was too severely extended. The arm should be removed from the splint on the third or fourth day, bathed, powdered, and adjusted. This should be repeated every two or three days thereafter. At the end of ten or twelve days certain exercises were begun, but no specific rules could be laid down for the manipulation of a fractured lower forearm or wrist, as all depended on the amount of injury to the member, the age of the patient, and the location of the injury. After showing the relation of the bones of the forearm and wrist to the splint, which showed that the device was not only constructed along normal anatomical lines but also embodied scientific principles, the speaker drew the following conclusions: 1. The arm and wrist were plumbed when properly adjusted. 2. A median line drawn along the dorsal aspect of the forearm, wrist, and hand, represented its center of gravity. 3. Tension along

said line was directly through its lifting power, and under these conditions could not deviate from a straight line. 4. If sufficient tension was applied to separate the fractured parts slightly the healing process would progress favorably and there would be practically no shortening by absorption of bone tissue. The most comfortable conditions possible were presented in this splint for making extension and counter extension; the hand was placed in a form specially shaped to receive it, a part of the fingers extending over the edge in depressions formed to receive them; the palm of the hand rested on a perfectly natural surface, the ball of the thumb coming into contact with a depression formed to receive it; the outside of the hand rested against a like surface. The obtuse angles to accommodate the hand and flexed condition of the wrist made a holding surface so extensive that there could be no undue pressure at any given point. The elevated sides of the splint received the wrist and retained it in a normal position.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held in Hartford, Conn., June 10, 11, 12, and 13, 1912.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. A. M. BLACKADER OF MONTREAL, IN THE CHAIR.

(*Continued from page 731.*)

Wednesday, June 12—Third Day.

An Impression of the Seventh International Congress on Tuberculosis, Held in Rome, April 14-21, 1912.—Dr. A. J. RICHER of Ste. Agathe des Monts, Canada, said that in spite of its sessions and the great number of contributions brought forward, this congress had not been productive of anything that could mark it as epoch-making. There were many contributions that were excellent but none that were exceptionally distinctive. The burning question of human and bovine tuberculosis supplied most of the material for discussion at the conference; when a compromise was finally reached in the way of resolutions they did not differ very materially from those of the Washington Congress. In the field of therapy many contributions dealt with artificial pneumothorax as giving very encouraging results in suitable advanced cases where the usual methods had failed. The action of solar light (heliotherapy) was made the subject of quite a number of papers and here the cases reported belonged to the surgical class. Rollier of Leysin attracted much attention by showing results obtained at his clinic in bone and joint tuberculosis by exposure to the sun's rays. Tuberculin-therapy and chemotherapy were fully discussed but no new light was thrown upon these modes of treatment. The organization of the congress was not as complete as had been hoped. The delegates from both American continents were royally looked after. It was decided to hold the next congress in London five years hence.

The Rôle Played by Resistance in Pulmonary Tuberculosis.—Dr. A. J. RICHER of Ste. Agathe des Monts, Canada, said that during the past ten years there had been a growing tendency toward the belief that tuberculous infection occurred during the first years of life. Clinically, the histories of patients had given his conception sufficient coloring to influence some clinicians to the partial acceptance of such a view. It remained for Calmette and his collaborators to give final conclusive proof in a series of experiments and tests performed at the Pasteur Institute at Lille which were summarized in *La Presse Médicale*. The conclusions might be summed up in the following manner: (1) Almost 90 per cent. of the children of school age reacted to tuberculin (cutaneous reaction). (2) The majority of implantations were of human origin. (3) With few exceptions, the pathway of infection had been the digestive tract. (4) Infection in early life conferred a degree of immunity if the doses of infective material were not large or rapidly successive. The resistance offered by children suffering from pulmonary tuberculosis was an incontestable fact; the only tendency was toward a spontaneous cure. Why, then, should this same disease in adults so frequently terminate fatally? Was it that the immunity of childhood had exhausted itself? Was it because the tissues of the adult differed so materially from those of the child? These two questions must for the present remain unanswered. Paterson of Frimley said that his method of treatment was based upon the question of resistance, how it could be raised by exercise and graduated labor until fever reactions occurred; the latter was controlled not simply by rest in bed but by complete immobilization. The system offered the following advantages: (1) The duration of treatment was about half what was needed for the continuous rest treatment. (2) Relapses were almost nil. (3) Employment during the treatment prevented the breeding of discontent and apathy. (4) Occupation of body and mind during the treatment permitted the patient to resume his former work untainted by the malady which the reclining chair bred, viz., disinclination for work. (5) No special climate was required. (6) Patients in the advanced stages of the disease had some chance of recovery. The outlook was thus more hopeful for all concerned. (7) The work performed by the patients lessened the cost of their maintenance quite materially. The Frimley method was applicable to all cases of pulmonary tuberculosis.

Dr. HERBERT MAXON KING of Liberty, N. Y., said that the work of Paterson was not particularly new. Exercises had been utilized as a method of treatment in pulmonary tuberculosis long ago. Whether the good results were due to the exercise, the autoinoculation, or the tuberculin he could not say. Their experience with the opsonic index was insufficient to prove anything. The great difficulty in the employment of exercise as a therapeutic measure was that they had no criteria as to the dosé to be prescribed, nor did they have any rule for the proper selection of patients. At the Loomis Sanitarium they had not found it applicable to all patients. Paterson did not rely upon the physical findings and he himself did not accept this view of things. He preferred to examine his patients once in a while and in many instances this had led to the exclusion of patients from the walking groups. It should be distinctly understood that this was not a method to be adopted immediately on the admission of the patient to the sanatorium. All patients required a preliminary period of rest. When they were in a quiescent condition they were urged to take the walking exercises prescribed. The patints grew tired of the walking and most of them preferred some diversion. Manual labor had been substituted, but he thought that where this was done for purposes of economy it was doomed to failure. They had never introduced this method of treatment into the main division of the sanatorium until last winter, when they had found the results most satisfactory. It did not seem that it would have been possible to discharge so many patients as they had during the past year had it not been for the walking groups. The chief value of this method was in estimating the capacity of the individual for returning to his normal occupation. The patients should be urged to maintain the same hours of rest and exercise outside as in the sanatorium. One could never tell until it was tried whether individuals would respond favorably to exercise or not. If the temperature rose to 101.5° F. and fell again within a half hour from the time after exercise it was considered safe to allow the patient to continue; if the temperature failed to return, they reduced the amount of exercise or stopped it altogether.

Dr. J. H. PRATT of Boston, Mass., said that Paterson deserved great credit for his work, but that he had been greatly misunderstood. He placed so much emphasis on exercise in his writings that rest was overlooked, whereas he selected his patients carefully and prescribed exercise only after they had had a long period of rest. What they needed were more facts; they should get statistics from the leading men covering at least forty years. Dr. Pratt said his own figures showed excellent results. In a class of 161 patients, 77 were restored with their wage earning power proven. The number reported permanently arrested and able to work from six months to six and one-half years was 69. There were only four deaths among those discharged after an average length of time of three and one-half years. Under the rest treatment the results were so good in the first and second stages of the disease that he wondered if the advocates of exercise could show as favorable ones. During the active stage of the disease the proper treatment was rest, as absolute as possible. When the temperature was normal and the pulse rate low, when immunity was established, and not until then, exercise might be begun. He frequently kept patients in bed four or five months.

Dr. HUGH M. KINGHORN of Saranac Lake, N. Y., said that exercise in the form of walking was employed by all lung specialists when the patient, in the opinion of the physician, was in a suitable condition to walk. It was a matter of judgment with the physician how much or how little walking his patient should take; it was also a matter of judgment at what stage in his treatment he should

begin to take exercise. The aim of the hygienic and dietetic treatment as practised by Dr. Trudeau and the Germans was directly opposed to the autoinoculation theory. There was no proof that these autoinoculations were of any value. The tuberculo-opsonic index had been proven by William H. Park, the Saranac Laboratory, and others, to have absolutely no value. As to the question of labor, a note of warning against its general adoption in the treatment of pulmonary tuberculosis should be sounded. The aim of the physician was to cause a cessation of active symptoms and of active disease, and to produce a staple condition and then a considerable period was necessary in order to fix this condition. The open air plan of treatment as practised by Brehmer, Detwetter, and Trudeau had stood the test of time and produced brilliant results and each year showed greater success because they used the great principles of rest, fresh air, and food with greater care.

Dr. J. N. Hall of Denver, Colo., said that he had been especially interested in the disease as it affected physicians. A number of the prominent Denver physicians had made complete recoveries from tuberculosis. He had had as many as one hundred physicians under his care; two of them had been there but a few years, but all the others had been there for five years or longer and they were all free from symptoms of tuberculosis. He believed that physicians made a better recovery than others; they probably recognized their condition earlier and came in time to be properly cared for.

Dr. Cleaveland Floyd of Boston, Mass., called attention to the comparative immunity of people during early life and he thought that without doubt children had a greater resistance to the spread of the disease and toward its arrest than had adults. There were two factors responsible, autoinoculation and the activity of the lymphatic system. If they could get more exact data in regard to rest and exercise, it would be a step forward; at present the questions had to be decided by the individual physician. It seemed to him that they could do better work if they could get a better blood picture. Exercise had been useful in telling him whether a patient was getting too much tuberculin. If they had some means of measuring the severity of infection in the individual case it would be a help. If they could isolate the tubercle bacilli and test them on the guinea pig they could get some idea of the intensity of virulence of the organism.

Dr. Carroll E. Edson of Denver, Colo., said that rest and exercise as therapeutic measures belonged rather to the art than to the science of medicine. They should not lose sight of the histology in these cases. The formation of scar tissue took time; it could not take place in a day or a week. The mere subsidence of the fever did not mean the formation of scar tissue.

Dr. Guy Hinsdale of Hot Springs, Va., thought there were some criticisms to be made of the method of graduated labor as used in this country. The cases at Frimley were chosen only after long periods of observation and after having a great deal of rest. The trouble in this country was that the cases were not properly selected, graduation of labor was not properly given, and in many institutions work was provided for economic reasons.

Dr. Lawrason Brown of Saranac Lake, N. Y., said that giving rest to the individual would do more toward stamping out tuberculosis than any attack on the tubercle bacillus. He doubted whether graded exercises were better than tuberculin. As to Dr. Paterson's cases not relapsing, he doubted this. They were not followed long enough. One could not tell the results of treatment in one, two, or three years. Paterson selected his cases carefully; he did not take those with large cavities, or physical signs at the top and bottom of the lung. Dr. Brown said he kept his patients quiet and did not use exercise for the purpose of autoinoculation but in order to prepare them to resume their work. He considered the workshop a blessing and the patients were put to such work as would develop the muscles that were usually involved and those that would be used in their future employment. He believed that all patients were autoinoculated. Exercise should be taken one day and followed by rest the next. No exercise should be ordered on the day that tuberculin was given.

Dr. Charles L. Minor of Asheville, N. C., said he was interested in what Dr. Floyd had said regarding the estimation of the resisting power of the patient. Much of value could be determined by watching the effects of exercise. He had never seen any of the bad effects from exercise properly controlled that he had from doses of tuberculin in susceptible patients.

Dr. A. J. Richer of Montreal, Canada, said he was pleased with the discussion that had been evoked. He had felt just as most of them did four years ago, but had changed his mind. He thought they would also be convinced if they read Dr. Paterson's book and if they saw the methods in application as he had seen them. The system as practised in England was not applicable in this country, but it could be adapted to the needs here.

Subsequent Histories of Tuberculous Cases Treated During Twenty Years (1891-1911) at the Sharon Sanatorium.—Dr. Vincent Y. Bowditch of Boston, Mass., and Dr. W. A. Griffin of Sharon, Mass., presented this communication. The paper was the result of an investigation of the present condition of patients discharged from the Sharon Sanatorium from the time of its foundation in 1891 to January 1, 1911; no patient was reported who had not been away from the sanatorium at least one year. There had been discharged 592 cases; of these 22 stayed so short a time that they were considered not treated. Nine others were admitted for some other complaint than tuberculosis of the lungs. Tenty-four did not react to tuberculin and were termed merely suspected cases. Seventeen in the early years of the sanatorium were discharged as well; these seventeen cases were considered in this report. This left 520 cases, of which forty-eight were discharged as not improved, 175 as improved, and 297 as arrested or apparently cured. Of the non-improved cases (48) all died as might be expected, 100 per cent. Of the improved cases (175) 107 died, 60 per cent.; condition reported good (51), 29 per cent. not traced (17), 9 per cent. At this time they had to report 297 arrested and apparently cured cases. Of the 297 cases, 25 had not been traced (8 per cent.), 35 had died (10 per cent.), leaving 237, or 81 per cent. alive and for the most part in excellent health. In reviewing the work accomplished in the last twenty years, they felt that their attitude had been one of conservatism as regards the results obtained. When one reflected upon the condition of affairs in the treatment of tuberculosis twenty or more years ago, and when one recalled the sense of hopelessness that was felt whenever a patient presented himself with symptoms of pulmonary disease, they felt that they were justified in looking with great satisfaction, even enthusiasm, upon the work of twenty years at the sanatorium. In stating their results it must be remembered that in using the term "arrested" they had applied it to the results obtained in many cases in which the physical signs and symptoms of the disease were well marked in spite of which condition a successful result was often obtained for a number of years. In such cases the surprising part had often been that they had remained so long without relapses upon resuming the ordinary conditions of life. They had no sympathy with the attitude that because sanatorium treatment had not proved to be a panacea, it had, therefore, failed in its purpose. On the contrary, with greater confidence than ever before they felt it to be one of the great and important factors to be resorted to in conjunction with every other known method of combating the disease which still held the highest place in the mortality list of the civilized world.

Dr. James M. Anders of Philadelphia, Pa., said that it was important to remember that sanatorium treatment did not cure patients but merely started them well in the treatment. After the patient left the sanatorium the physician still had a very important duty to perform in instructing him how to live. The patient should be made to understand the necessity of keeping himself in good physical trim. This meant that he should maintain good muscular development. These patients required walking, rest, and recreation.

The Treatment of Arteriosclerosis.—Dr. Thomas D. Coleman of Augusta, Ga., read this paper. He did not wish to discourage the use of the blood pressure apparatus; it was a very valuable instrument. No instrument could take the place of the finger, nor could any instrument teach as much about the pulse as could be learned by palpation. Daland had shown that the mere application of the cuff in certain neurotic subjects often increased the blood pressure as much as 30 to 40 mm. The widest field for good lay in the prevention rather than the cure of arteriosclerosis. All causes which they knew operated to produce the condition should be curtailed or eliminated as far as possible. There were two parties to this problem: the physician as the educator, and the individual who was willing to profit by his advice. Excesses of all kinds, mental as well as physical, should be shunned. Alcohol, coffee, tea, and tobacco should be used in moderation, if at all. The treatment of arteriosclerosis might conveniently be divided into hygienic, dietetic, and medicinal. Every healthy individual required a certain amount of exercise and the kind and amount should be adjusted to meet the demands of the individual. The mental and physical activities of the individual must be carefully directed. It was a fact that the majority of persons ate too much and nearly all ate too rapidly. In

general meat should be indulged in sparingly. In advanced cases, a rigidly restricted diet was at times imperative. Nitroglycerin acted quickly and might be employed for a long time; its chief drawback, however, was its evanescence. It rapidly caused dilatation of the peripheral vessels, and if pushed sufficiently far would cause flushing of the face, headache, etc. The more lasting effects of the nitrites made them more preferable.

Dr. James M. Anders of Philadelphia, Pa., said he agreed with Dr. Coleman that the instrumental measure of blood pressure was after all less valuable than careful palpation; palpation enabled them to estimate the degree of tension by distinguishing between actual arteriosclerosis and high tension, and this was a very important matter from the standpoint of treatment. The successful treatment of arteriosclerosis was the treatment of the cause. The strenuous life of the day was among the chief causes of this condition. In many cases due to this cause the rest treatment, together with vasodilators was highly successful. At the same time they should give a general diet that would replenish the patient's energy. The prolonged use of sodium nitrite would benefit these patients; it seemed to soften the vascular walls and to reduce the viscosity of the blood. If this agent disagreed with the stomach function it might do more harm than good. The benefits derived from sodium nitrite were more lasting than those obtained from nitroglycerin.

Dr. I. Jacobi of New York said that the only preventive of arteriosclerosis was to diet in time. Arteriosclerosis began at about the thirty-fifth year and it appeared in almost everyone, whether the individual realized it or not. If the person was unconscious of having the condition it was because it was less generally disseminated and more localized in certain spots. So far as the treatment was concerned they had been told to avoid large meals and to eat slowly. Few American knew how to eat, especially doctors. One should eat slowly and not drink too much. Dr. Jacobi said he told his patients to take a glass of water and divide it into six parts and then to drink one part every ten minutes. The speaker said he had taken iodine for six months in succession; he could not take iodide of potassium and he had seen many patients who could not take it. He had also found that the alkaline salts of sodium in small quantities were valuable. He had seen men seventy or seventy-five years of age with intense symptoms of arteriosclerosis living a comfortable life and attending to their business while taking this preparation. The attacks of arteriosclerosis caused by deposits in the coronary arteries leading to angina might be relieved by doses of nitrites with morphine. He gave one-quarter of a grain of morphine and 1/100 to 1/50 of a grain of atropine, having the patient place it on the tongue and suck it down slowly. He allowed his patients to have a dozen tablets and to use one when the attack came on.

Dr. Charles L. Minor of Asheville, N. C., said that people led such foolish lives in this country that it was useless to speak of prophylaxis. He had found that iodide of potassium in three-grain doses was of considerable value, but that the combination of dietetic and psychical treatment was of greater value. If they followed the English way of living there would be less arteriosclerosis. The physician should tell his patients how to live; sometimes the advice would be followed, ofttimes it would not. Two meals instead of three should be taken, heating foods and cocktails should be avoided, and the patient should be careful not to overeat.

Dr. Thomas Darlington of New York, said he had been interested in the question of longevity and had questioned the members of a family many of whom were very long lived. Three of these were 100, 101, and 103 years, respectively, while four were over 90 years of age, and five others over 86. They all gave practically the same experience and their advice was to eat slowly and sparingly and to keep the bowels open.

Dr. Edward R. Baldwin of Saranac Lake, N. Y., said that in institutions the inmates were very prone to overeat and he had observed that this was an important factor in the production of arteriosclerosis.

Dr. Guy Hinsdale of Hot Springs, Va., said that anyone who practised medicine at a health resort saw many of these cases of arteriosclerosis. A large number came to these resorts for hydrotherapy. Dr. Swan had told him of his experience with the carbonated baths and they did not seem to affect the blood pressure one way or the other. The relation between these baths and blood pressure seemed to be very hazy. It would be desirable to arrive at some definite conclusion regarding their effects.

Dr. J. H. Pratt of Boston, Mass., said he had made many observations on the blood pressure before and after giving the carbonated baths and he was sure that a course of baths had no permanent effect on the blood pressure of any therapeutic value. The immediate effect of the baths was striking. If the patient had a normal heart and was given a full strength bath at a temperature of 93° F. there would be a rise in blood pressure; if the heart was weak the full strength bath would be followed by a fall in the blood pressure. It had been shown that the temperature had a marked effect on the blood pressure, as much so as the carbon dioxide gas.

(To be continued.)

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

International Clinics. Vol. III. 22nd Series. Edited by Henry W. Cattell, A.M., M.D. 306 pages; illustrated; cloth; price $2.00 net. J. B. Lippincott Company, Publishers, Philadelphia.

Ein Weiterer Beitrag zur Glaukom-Frage. By Dr. W. Wagner. 45 pages; paper; price 1.50 M. S. Karger, Publisher, Berlin.

Elementary Bacteriology and Protozoology. By Herbert Fox, M.D. 237 pages; illustrated with 67 engravings and 5 colored plates; cloth. Lea & Febiger, Publishers, Philadelphia and New York.

Principles of Human Physiology. By Ernest H. Starling, M.D., F.R.C.P., F.R.S., Hon. M.D. 1,423 pages; illustrated; cloth. Lea & Febiger, Publishers, Philadelphia and New York.

Autointoxication and Disintoxication. By Dr. G. Guelpa. 152 pages; cloth; price $1.25 net. Rebman Company, Publishers, New York.

The Therapy of Syphilis. By Dr. Paul Mulzer. 248 pages; cloth; price $1.50 net. Rebman Company, Publishers, New York.

Miscellany.

Bergson on the Interpretation of Life.—The discussion recently held before the British Association for the Advancement of Science, served at least to bring out one important fact, namely, that notwithstanding the increasing knowledge of biological phenomena, the question of the origin of life is still enshrouded in mystery. The limitations of the human mind apparently decree that this question will ever be an elusive one. An admirable discussion of this phase of the subject is presented by Henri Bergson in his "Creative Evolution." He notes that "the human intellect feels at home among inanimate objects, more especially among solids, where our action finds its fulcrum and our industry its tools; that our logic is, preeminently, the logic of solids; that, consequently, our intellect triumphs in geometry, wherein is revealed the kinship of logical thought with unorganized matter, and where the intellect has only to follow its natural movement, after the lightest possible contact with experience, in order to go from discovery to discovery, sure that experience is following behind it and will justify it invariably. But from this it must also follow that our thought, in its purely logical form, is incapable of presenting the true nature of life, the full meaning of the evolutionary movement. Created by life, in definite circumstance, to act on definite things, how can it embrace life, of which it is only an emanation or an aspect? Deposited by the evolutionary movement in the course of its way, how can it be applied to the evolutionary movement itself? As well contend that the part is equal to the whole, that the effect can absorb its cause, or that the pebble left on the beach displays the form of the wave that brought it there. In fact, we do indeed feel that not one of the categories of our thought —unity, multiplicity, mechanical causality, intelligent finality, etc.—applies exactly to the things of life: who can say where individuality begins and ends, whether the living being is one or many, whether it is the cells which associate themselves into the organism or the organism which dissociates itself into cells? In vain we force the living into this or that one of our moulds. All the moulds crack. They are too narrow, above all too rigid, for what we try to put into them. Our reasoning, so sure of itself among things inert, feels ill at ease on this new ground. It would be difficult to cite a biological discovery due to pure reasoning. And most often, when experience has finally shown us how life goes to work to obtain a certain result, we find its way of working is just that of which we should never have thought."

Classical Training and the Physician.—H. D. Rolleston ventures the opinion that, valuable as a really good classical training is in some respects and attractive as its advantages are in brilliant exceptions, the bulk of medical men pay somewhat dearly for the luxury of any aroma of classical culture which still clings to them in late middle life to compensate for the years spent at school and sometimes at the University on the dead and difficult languages. A large proportion of medical men have almost entirely forgotten the Greek they once knew, or at most can recall just enough to understand and spell the never-ending flow of new and often unnecessary medical words, some of which bear witness to their inventors' originality in being composed of the Greek termination *itis* appended to a Latin noun or even a comparatively modern name; such are Bartholinitis and Wirsungitis. Latin is more familiar, but largely because prescriptions are still supposed to be concealed from the public by the garb of Latin words often discreetly and somewhat illegibly abbreviated. It may safely be concluded that to the ordinary medical man the direct or marketable advantage of a classical training is entirely out of proportion to the amount of time commonly devoted to it. But it is often urged that, apart from any intrinsic use, the classical languages, in virtue of their peculiar structure, give a mental training and discipline which cannot be obtained from the study of French and German. This statement is difficult to prove, and we have the high authority of Sir Clifford Allbutt for the dicta that "it is not so much *what* a man is taught as *how* he is taught it," and that "the current teaching of Greek and Latin is a parody of education; not only does it restrict the range of the teacher and pupil, but the imaginations of both are stunted." After nearly 20 years' experience as a master at Eton, A. C. Benson frankly characterizes the results of the classical routine as "intellectual starvation." In spite of what has been said about the drawbacks of a prolonged and exclusively classical education, this decision is probably beneficial as regards the elementary education of future medical students, for there is much to be said in favor of retaining the classical languages so long as the teaching of French and German and science is not interfered with or delayed.—*The Lancet,* October 5, 1912.

Doctor and Patient.—Dr. James G. Mumford, in the latest product of his versatile pen, entitled "A Doctor's Table Talk," notes that "the physician at a patient's house, on the one hand, or in his own office on the other, occupies somewhat different rôles; not that in the one case he is guest and in the other case host, though in some slight measure that is the fact, but because the doctor has far better control of his patient and of his own time at her house than in his office. Observe the 'her.' The majority of calls are from women. When at her house you ask your questions, make your examinations, give your directions and go. Prompt, kindly expedition gives a sense of your efficiency and dignity. Rarely is it necessary to stop for gossip. In your office, on the other hand, you may be at the mercy of a heedless or selfish patient. A very busy consultant, with a trained office attendant, can have patients shown in and out rapidly at the touch of a bell; but the average practitioner, with his small and irregular office practice, must suffer the whims of the heathen. Don't hurt their feelings unless they be mere humbugs and bores. Bear with them as long as you think proper, then rise and get rid of them by the plain statement that you are busy, or that patients by appointment are awaiting you—as the case may be, and you will see them again that day week. Some day I must write a book on the misery of a doctor's consulting room from the doctor's point of view. In these days of trained nurses and social service workers it is comparatively easy to get your directions for treatment carried out in the case of bed patients and of serious illness; but in the case of office patients you are never sure. Write out full and explicit directions for every patient, whether he has a nurse or not. Thus will you be sure of obedience. The *spoken* word is as snow in the desert."

THE DIAGNOSIS OF MENTAL CONDITIONS.

BY HENRY M. FRIEDMAN, M.D., LL.B.,

NEW YORK.

ACTING ASSISTANT SURGEON, U. S. PUBLIC HEALTH SERVICE.

IN the diagnosis of mental conditions, more than in any other pathological conditions, the individual himself must be the chief point of consideration. The long strides in the laboratory or scientific diagnosis of disease have brought about a tendency to forget the patient himself and to consider him only in the light of a "case" in the abstract. Thus far, however, the inroads of science have committed little, if any, depredations in the field of psychiatry, for with a few exceptions no one can say with what pathological conditions he is dealing, or even what the etiology of a given case is. Of necessity, therefore, the physician is brought face to face with the patient himself; that is, with his antecedents, environment, habits, education, etc.

Moreover, the many features that must be considered, and the frequent deprivation of liberty and property accompanying such a diagnosis make it imperative that a diagnosis of disease of the mind be made only by trained experts after due observation. "Snap diagnosis" must never be made. It is an unfortunate fact that even after the most careful observation by the best men mistakes are only too frequent. On the other hand, opinions of sanity or insanity given by lay people, whether they be physicians not trained in psychiatry or by judicial officers, juries, or the average citizen, have only too often been proven fallacious and productive of great harm to the public. Psychiatry is really a profession by itself. A physician is more fitted for this work only because his profession brings him into closer relations with his patient than any other person. He is the only one who has learned to view mental and physical ills with an analytical eye. Here, more than in any other branch of the medical sciences, is experience so essential to success. For in spite of the many vagaries, mental disease follows certain lines, and while no two manifestations are exactly alike—a condition also true of the physical ills—yet alienists who are familiar with these lines are better able to ferret out the disease than those who have not had similar training and experience. In psychiatry specialization should be aimed at just as specialization and not versatility is required in almost every walk of life. Each branch of science is so vast, each new discovery opening the door to trackless fields of research, that no one can hope to be proficient in even one of its branches without endeavoring to master many. The vanity of laymen, therefore, which permits them to pass opinions on topics on which men have spent lifetimes without venturing such definite opinions, is, to say the least, inconsistent with enlightenment. "Fools rush in where wise men fear to tread."

In the consideration of this subject the various insane, dementive, and maniacal manifestations, as well as idiocy and imbecility, can be left out of the discussion; likewise the differential diagnosis between the various clinical forms of mental derangement. Society is only interested in knowing whether an individual is sane or insane and not in the clinical variety. When the disease is in a state of dementia or maniacal excitation it is a physical manifestation rather than a mental one, though the underlying cause is mental. The differential diagnosis can be made only after long observation and is merely of scientific or prognostic value. The various mental conditions manifested by delusions and feeble-mindedness and backward or retarded mentality give the greatest difficulty in diagnosis. In mental disease it is a composite picture with which we are dealing. No one symptom is diagnostic of the disease—there are few, if any, pathognomonic signs. The points to be considered, and from which the composite picture of mental disorder is drawn, are heredity, race, environment, temperament and habits, education, and physical condition. Not one of these items alone is of value in making a diagnosis; only the combined results of investigations along these lines are of service in arriving at a diagnosis.

Heredity especially plays an important part in diseases of the mind. In no other condition has the hereditary transmission of disease received so many practical demonstrations. A number of writers have demonstrated this fact, and only recently Goddard succeeded in tracing the genealogy of feeble-minded children to their insane or defective ancestors a number of generations back.[2] It is now universally conceded that deficient mental make-up is very likely to beget a similar life, and that, too, whether the deficiency is prenatal in origin or acquired through disease, or alcoholic or other indulgence. Yet it is an inexplicable fact that many great men have had mentally defective antecedents or collateral relations. And, indeed, some of the greatest men themselves have been considered mental defectives. The question that is so difficult to decide is whether, in a given individual, a family history of mental disease should determine in him a diagnosis of mental disorder, where otherwise it would be in doubt or not made at all. Shall such a history be a clinching point in an otherwise doubtful case? The whole subject of heredity is still so veiled in mystery that positive opinions cannot be ventured. However, from practical demonstrations along these lines the preponderance of evidence lies with those who lay great weight on heredity in the etiology and diagnosis of diseases of the mind.

Habit, temperament, and racial and environmental

characteristics are important factors in diagnosis. Unless we know the normal we cannot distinguish the abnormal. An abnormality in one individual might be a normality in another. Insanity is really a straying from one's own normal. There is no normal that applies to every individual; that is, there is no standard, even in people of the same race or type. If one were always a "dreamer" only a radical variation from the "dreams" would be abnormal. The same "dreams," however, in some other individual not similarly constituted would spell a disordered condition of the mind. Some races of people are extremely emotional and excitable; others very dull and phlegmatic. The emotionality of the Hebrew or southern Italian is too well known to need elaboration. It is not uncommon to excite in them an action almost maniacal in nature on the slightest provocation. On the other hand, emotional excitations in the more phlegmatic races should always arouse suspicion of mental aberration. In this work the need of knowing the people with whom one is dealing cannot be too greatly emphasized.

The main symptom, generally speaking, upon which the diagnosis of mental disorder is made is the delusion. A delusion is a fixed idea not based on fact, which cannot be righted by reason. The insane, in other words, are not amenable to reason. Usually the most difficult cases are those in which there is a delusion on one subject only—paranoid types—while otherwise the patient appears rational. Why a person should have a delusion on one subject only or on one train of thought and be rational on all others is not quite clear. However, the mind is undoubtedly made up of a great many mental organs, so to speak—perceptive and receptive faculties—and it is reasonable to conceive of disorder in any one of these organs which does not apparently affect the others. The single delusion corresponds to the single mental organ which controls the particular receptive or perceptive faculty involved. In the body, likewise, a single organ may be disordered while the other organs are not directly affected, and indirectly so slightly that symptoms are not apparent. Still, while there may be but one delusion, and the individual may appear otherwise normal, there can be no doubt that, owing to the close association of all the mental faculties, an affection of one will have a deleterious influence on the whole mental apparatus. The individual, therefore, with but a single delusion should nevertheless be considered entirely disordered and not merely partially. At any time the obsession of one part of the mind may spread to others, just as inflammations in one part of the body have a tendency to spread to other parts either by continuity or by sympathy. Acts committed having no direct connection with the delusion are undoubtedly influenced by the pathological condition causing that delusion.

In establishing that a certain idea of the patient is a delusion or a certain act irrational, it is of course first necessary to establish the falsity or irrationality of the idea or act. Delusions are either possible or impossible ideas. In the latter there is little doubt, on hearing the idea expressed, in relegating the individual to the class of the mentally deranged. The former, however, because in the abstract they are perfectly possible ideas, are the ones that give the greatest trouble; these are the instances that are so hard to prove to outsiders. Many a delusional or irrational action is but an exaggeration of a normal or possible idea or act. A perfectly normal idea may be exaggerated yet not so unreasonably so as to constitute a psychosis. But if this idea is very greatly exaggerated it may then bear little or no resemblance to the original idea and be then really irrational or delusional. In many individuals who are constitutionally inferior, who have a weak mental organization, that is, those who are weak-willed and easily influenced, those who have the so-called psychopathic tendencies, this is particularly liable to occur, especially under conditions of mental or physical stress. In these individuals the imagination is heightened, exaggeration is easily stimulated, and finally, possibly from the frequency of such stimulations, they are unable to distinguish between the imagined idea and the fact; that is, they become obsessed with the imagined idea—the delusion.

While the establishment of the delusional nature of an idea or the irrationality of an action usually decides the question of insanity, yet in most instances the difficulty lies in finding the delusion. An insane person of previous average intelligence is usually well orientated on all subjects. He very soon learns which of his beliefs are considered delusional and are liable to get him into trouble. These he endeavors to hide just as a criminal tries to conceal the facts or evidence tending to betray him. Their cunning is ofttimes extreme and must be matched by that of the examiner if the former is to be caught. The patient is able to detect that others are gunning for his delusions, and he only too frequently manages to evade his "pursuers." At other times, while the patient is not attempting to conceal his delusions or does not suspect the purpose of the interrogation, the examiner may be unfortunate in not striking a line of questioning which would elicit the delusion. This the examiner may not be able to do because he is not familiar with the habits or customs around which that particular patient's delusion is woven. The delusion may be centered around a peculiar and possibly insignificant religious or race custom, of which the examiner could not possibly be informed and could not, therefore, direct his efforts in that direction.

A phase in the diagnosis of mental conditions, which usually arises in the probate of wills, is the determination of the actual mental condition of the so-called eccentric. To distinguish between eccentricity and insanity is at times well nigh impossible, for the reason that such individuals rarely commit acts that conflict directly with anyone, and their condition thus rarely becomes the subject of scrutiny. At times the eccentric will do things far more unreasonable than the admittedly irrational. Whether an eccentric action or idea is not such an action or idea as cannot be altered by reason is not easy to decide. There can be no doubt that in the broad treatment of this subject all persons who are "queer," "peculiar" or "eccentric" are such persons as have to a greater or lesser extent lost the mental equilibrium which goes to make up the normal clearsighted individual, but not such a disorganization as to lose entire control of any mental faculty or faculties. In will cases the contestants try to prove, by a plainly irrational act, that the deceased's eccentricity was tantamount to insanity. In deciding the mental status of the eccentric, however, it is safest to err on the side of the suspected individual, because of the indefinitiveness of the whole subject of insanity, especially if he does not act in conflict with the public.

In considering the diagnosis of the actual mental defectives—the idiots, the imbeciles, and the feeble-

minded—the first two give little difficulty. Besides the lack of any, or in the case of imbeciles very little, mental development they usually present definite physical or facial characteristics which leave little or no room to doubt the nature of their condition. The difficulty lies in making the distinction between the feeble-minded, who have just overstepped the line to the side of the defective, and the backward, who are still on the normal side of the line. The dividing line between the two is sometimes very fine. In enfeeblement there is a mental development but limited in amount. In backwardness or retarded mental development, the mental development is not limited, only it is a few years short of the average or normal. Feeble-mindedness is a limited mental development; backwardness is tardiness in mental development. Practically speaking, feeble-mindedness and backwardness are relative conditions. The mental condition of a child brought up in a sphere of education and culture might be so poor, by comparison at least, as to amount to a positive enfeeblement. Yet the same degree of mental development in a peasant type of child, brought up in its own sphere of ignorance, would be very good indeed. Ultimately, of course, the latter child, assuming that it has a normal mind, would develop almost indefinitely, while the former would not. The difficulty lies, therefore, in distinguishing between a positive enfeeblement and mere retardation to a certain degree. The detection of mentally defective children in early life is almost impossible; in all likelihood it cannot be done before the age of three or four, though the deficiency exist from birth. In early life two apparently equally dull children react differently to educative influences. The one may brighten up remarkably and become an average, and frequently above the average, individual. The other, who can later be identified among the feeble, remains in the original condition in spite of the educational efforts. At the present time, and as illustrative of the difficulty of determining the feeble-minded, they are being educated sufficiently to be self-supporting. Such individuals might baffle diagnosis and would even compare favorably with normal, but ignorant children. It is almost an easier task to educate children who are inherently backward, in an environment of culture, than normal children in an environment of ignorance.

In feeble-mindedness, as distinguished from backwardness, the brain contains, so to speak, only a limited amount of raw material from which the mental faculties can be developed. Such individuals' maximum mental development is reached very early, and no amount of education can stimulate very much further development. Backward children, however, merely start with a *minus* in their mentality, which may or may not increase as the child grows older, and continue in early life at least in this condition. In most instances they can catch up with the normal child, especially with the aid of specially devised educational methods. The backward child develops on the application of a little more mental stimulus; the feeble-minded will not. Backward children need more education and a little more trouble in the application of it. Still, even if the child does not catch up and goes through life with a few years of retardation in its mental development, this is not of much moment, for the possibilities of mental development are almost infinite. Besides, in the face of the profoundly intellectual we are all more or less backward!

In endeavoring to determine the mental condition of a child, the first essential is to determine how much a child of similar age, environment, mental education—and especially opportunity—knows before one can determine the condition of the child in question. Comparison of the child with children of the same family furnishes, when possible, an excellent basis for comparison. A marked difference is very significant of defect. Yet, many children who, during school life, were considered defective, or who compared very unfavorably with their mates, succeeded in later life even from the standpoint of mental accomplishments. Realizing the difficulty of determining the mental defectives by the present indefinite means of diagnosis, Binet, in conjunction with Simon, devised a system whereby they hoped to determine from a standard, which they established in accordance with the age of a normal child, the degree of mental development of the child under test.[1] For the purposes of these tests Binet divides his subjects into three classes: Those in whom there is a general retardation both mental and physical; those in whom there is a retardation in one mental faculty more than in others, and those in whom all the mental faculties show retardation. He makes another classification—those whose intelligence is retarded; those who are unruly, inattentive or mischievous, and those who represent combinations of both types. The mentally defective of the retarded-intelligence type are more numerous as the children are older, and vice versa for the unruly ones, or, as Binet calls them, "the instabiles." The retarded-intelligence type, though attentive, learn less than other children under the same instruction. Concerning these children the teachers usually give good reports as regards their attentiveness, willingness, and behavior. "The instabiles" do not learn, for the apparent reason at least that they do not apply themselves to study, though they sometimes appear brighter than normal children.

After establishing the standard with normal children of successive ages, Binet shows the child to be tested a picture of familiar objects, and after a lapse of a definite time—thirty seconds—asks the child to repeat to him from memory what he saw thereon. The degree of retardation depends on the number of objects he can remember, as compared with the number a normal child can remember. If an eight-year-old child can remember only as much as a normal five-year-old child, the former is retarded three years. A retardation of ten years is considered a permanent defect or enfeeblement. The picture test is supplemented by having the child repeat spoken or written words; the number of words that can be repeated from memory, as compared with the standard child, determines the degree of retardation. These tests are elaborated, standardized, and tabulated up to the age of sixteen, and can thus be applied by anyone. Goddard, with his own modification, has these tests applied by girls specially trained for this work, but having neither medical nor psychiatric training.[3,4] Following out the scheme they are able to tabulate very rapidly the degree of mental efficiency of a great number of children. This method might be used to advantage in the school system in keeping a record of the mental development of each child, just as is now done with the physical development. The whole scheme of these tests is the ascertainment of the approximate mental age of the child by comparing its attainments with those of a normal child

used as a control. The tests are especially of value in the separation at school of the mentally defective from the normal, in order that the former may not impede the educational progress of the rest of the children.

But the principle in the application of the Binet system in ascertaining mental acuity is not entirely new. It is applied every day in the competitive tests of our educational system, as exemplified in periodic ratings. The various civil competitive examinations also aim to pick out the better mentally from the poorer and economically to use the services of the better. As an actual scientific determination of the mental development of the child the Binet system still fails because it is too arbitrary for so elastic and complex an organization as the mind. Its use can only be restricted, as indeed Binet intended it to be, to the approximate determination of the child's mental acuity. The diagnosis of the mentally defective cannot be made from one examination. Only after watching the educational progress, under reinforced educational methods, can a determination be arrived at.

Coming to another phase in the diagnosis of mental conditions, namely, their detection by mere inspection of a great number of people as they pass in review before the examiner, it might be well to note that in the diagnosis of diseases of the body the recent scientific developments have had a tendency to defer the making of a diagnosis or even an attempt at one until the reports on the various laboratory or mechanical examinations have been made. And very recently a number of writers have called attention, in spite of these developments, to the value and good results obtained from inspection of the patient himself.[5] Furthermore, in the need for the detection and exclusion of physically, and especially mentally defective aliens—but owing to the impossibility of actually examining each individual because of the vast number entering—the method of the detection of disease or defect by mere inspection has been developed on a large scale. The great number of abnormal conditions thus detected is the best testimonial of the value of this method.

In detecting mental conditions almost as much can be learned from inspection, before the subject's attention has been attracted and while he is still at ease, as from prolonged examination. In the delusional types of insanity, where the patient usually realizes the purpose of the interrogation, prolonged examinations tend to increase his suspicions and often result in the successful concealment of the delusions. The detection of mental conditions among aliens requires special training in racial types and characteristics, even more than psychiatric training. Even with this training the difficulty of detection is very great when we consider that the physician of an institution or the alienist makes his diagnoses from persons sent to him because of some irrational action or speech. Furthermore, he works with a suspect and usually has a definite personal and family history with which to work. Yet, even under these conditions diagnoses are difficult to make and mistakes are very possible.

One of the most important signs, if not the most important index, of the state of the mind is the facial expression. Normally the face expresses, in a degree at least, the state or condition of the mind; in other words, the degree of intelligence. We even speak of reading the thoughts of an individual from the expression on the face. We have depicted on the face expressions of fear, anger, exultation, depression, etc. If, therefore, we determine what the normal condition of the mind should be under the conditions holding at the time, the facial expression will indicate variation and become a valuable clue to follow for further investigation. For example, the normal expression of apprehension and alertness of a Hebrew should be looked for; an indifference to surroundings and conditions should excite suspicion in the mind of the examiner. Similarly apprehension or alertness in a Greek or Macedonian is unusual, because his normal expression is rather dull or phlegmatic. Individuals exhibiting expressions of unusual excitation or depression should always be given a complete mental examination. Familiarity with the type or race under consideration is therefore absolutely essential. It is almost out of the question for an examiner not familiar, say with a Syrian peasant type, to form any opinion of the mental caliber of such an individual from his appearance or attitude.

The mental reaction or reaction time is another important consideration in the detection of the mentally unfit. The reaction time is the small, but still appreciable, period elapsing between the putting of a question and its comprehension and answer. In estimating the reaction time of an individual, his race and temperament must again be taken into consideration. The reaction time of a backwoods peasant is of necessity much slower than even that of a much duller individual from the city. Still, even an apparently dull person should, if mentally normal, brighten up appreciably on comprehending the question asked; a distinct "lightening up" of the face should then become apparent. An unusually long reaction time should be sufficient cause for a further and complete mental examination. Conversation, no matter how short, is extremely important in ferreting out mental conditions. It is, of course, the *sine qua non* of psychiatric examinations. Especially is this important in detecting dementive or enfeebled mental conditions, for here the lack or deficiency of the mind can thus be brought out. In diseases of the body diagnoses are usually made with the body at rest. In diseases of the mind, on the contrary, the diagnosis is best made with the mind in action. And speech is, of course, the mind's principal manifestation or translation of that action. In the very nature of the thing communion with the subject is absolutely essential. The difficulty in carrying out this essential lies in the many and diverse languages spoken by the people to be examined, and the necessity, therefore, for employing intermediaries, *i.e.* interpreters. This is far from satisfactory. As a matter of fact, no one can convey to another a thought as accurately through an interpreter as by personal conversation. Part of the thought or question is lost in its passage from the examiner to the subject through the interpreter. Similarly the answer loses in its travel. Very often it is the important thought, that for which the examiner is seeking, and which the interpreter considers too unimportant to transmit. Ability to speak the language of the subject is very desirable if for no other reason than that it gains his confidence, without which, when the subject examined is in a state of apprehension, little can be accomplished. Interpreters who are not familiar, from experience at least, with the trend of mental examinations are

of little help, if not a positive hindrance. Most of the makeshift interpreters will rarely interpret what the examiner says, and still less frequently what the subject says *as he says it*. They make their own interpretations of what is said, instead of transmitting exactly what is spoken. If the individual does not make what to them is a satisfactory answer, they will prompt and dicker with him until such an answer is made. Untrained interpreters fail altogether to realize that it is entirely the unsatisfactory and not-to-the-point answer that is desired. Moreover, the dickering breaks the trend of the subject's thought, and thereafter further examination at that sitting is of no avail. It is always desirable to let the individual have his say without interruption, since it is not a rational or coherent answer that is sought, but only his own answer, whatever that be. It is, so to speak, well to let him "incriminate" himself before commencing "cross-examination." Through conversation it is hoped to detect a rent in the train of thought or reasoning power. A break, no matter how small, denotes a weakness in the mental organization, and further examination along proper lines will usually reveal the disorganization. The line of conversation should be gauged strictly along topics with which the individual is familiar. A normal individual, no matter how ignorant, is orientated on the circumstances immediately surrounding his present status, while the disordered will display disorganization or disorientation of one form or another. When an individual shows some incoherence or hesitation in the primary questioning it should be followed up by a more thorough secondary examination. In this examination it is well to lead to, and follow up, circumstances immediately preceding present conditions and to determine the orientation on those matters. The primary questioning can be carried out in almost a few seconds; the secondary should be a lengthy one. An individual who is orientated on present—that is, more recent—circumstances, is not likely to falter on preceding conditions with which he is more familiar. At all events it is impracticable, though theoretically essential, to consider every alien a possible mental case and to subject him primarily to a complete mental examination unless on primary examination there were some signs of mental disorder.

In the detection of enfeebled mental conditions, appearance and attitude help somewhat, but in the high grade of enfeeblement it is a negligible quantity. An expressionless face reflecting no cognizance of surroundings or circumstances is always significant of mental deficiency. But conversation is here also an all-important factor in determining mental acuity. Here, especially, must the mental attainments of a normal child, with like mental education and opportunity, be borne in mind before we can judge how much lower the subject is in the mental scale. There is no definite method of determining this; it remains a matter of judgment and experience with the examiner after all the factors of race, previous environment, and education have been considered. Peasant children, for example, are not to be expected to show up as well as city children. If these reservations were not made the number of suspected cases would be very large, but the number of errors would be very great indeed. In short, in detecting mental conditions by inspection the first essential is to determine the race or type of the individual and his particular characteristics. Then note the facial expression and attitude, which would convey the impression of cognizance of environment and circumstances—an expression of "understanding." A few questions will determine the reaction time and orientation. If from these points nothing abnormal is noted the individual is allowed to pass, otherwise a further and complete mental examination is made.

The utilization of the Binet system on those who have been turned aside for a further mental examination is not as practicable as with school children. The Binet system was originally devised for school purposes in sifting and segregating the defective or retarded from the normal. School children are usually of the same type, either from similarity of race or environmental influences, and—what is especially significant—speak the same language. In the work of sifting aliens, one sees a kaleidoscopic array of people to whom one standard, or in fact any standard, cannot be applied. Were it possible to devise a Binet system standardized for each race or type, it would then be of great value. For, in principle the Binet system strives only to ascertain the comparative mental acuity of the child when compared with a normal standard *of its own sphere*. There is no standard normal child, i.e. one that is standard for all children. Many children make a poor showing under these tests because unable to understand what is wanted of them. Natural fear in their new surroundings militates against them. Even the most intelligent—and they especially—in fear of what they believe would be the consequences of a wrong answer, become too "nervous" to make a creditable showing. All of us who have taken examinations know how flighty our knowledge becomes at the examination door. The ability to repeat from memory, in the alloted time, would depend largely on the familiarity of the individual with the test objects. Indeed, ignorance of the peasantry from some places is extreme and this test would not be likely to elicit their real reaction time.

When the last word is said on the Binet system, as an aid in determining mental efficiency, it will be found that not the ability to remember words, pictures, numbers, etc., is an index of mental development, but only the ability to reason out simple mental problems. Some very bright minds are unable to do simple arithmetical sums without the use of pencil and paper. Reasoning power is the ability to place together abstract and previously separated but known facts, and to form from them the concrete thought; that is, it is the individual's power of association, and is equivalent to his degree of intelligence. This power is of gradual development in the human being. As the child grows older it should be able to reason out more difficult problems, those bearing a relation to its particular cycle of life. And the determination of this power lies almost entirely in the ability and judgment of the examiner, and not yet in any fixed scheme or system devised for application by anyone.

Conclusion.—The matter of the diagnosis of mental conditions, whether in institutions after prolonged observation or by the method of inspection, is difficult and often unsatisfactory. If it is difficult, even with the modern scientific aids, to diagnose present and patent diseases of the body, how hard must it be to detect intangible

mental disease without laboratory or scientific helps. Most physical ills give premonitory symptoms. In mental diseases, if there are such symptoms the patient is little likely to complain of them or seek advice on account of them, as he is so apt to do in the somatic ills. Moreover, he is more often against the physician than with him. Likewise, the detection of mental disease among aliens offers the same difficulties only in an infinitely larger degree. The goal in this work is to be able to detect from the panorama of people those who have remote or even latently present mental abnormalities. There are no signs by which an examiner can say in any given instance that an individual will develop a mental disease. The terms, mental instability, constitutional inferiority and psychopathic tendencies, as forerunners of insanity, refer to individuals whose mental organization is of the weakest; who, while they show no present symptoms of mental disorder, or who could go on mentally normal, for them at least, in primitive surroundings, yet on slight stress, such as they meet on encountering the hardships, and the increasing demands on their mental vitality, of settlement, become mentally disordered. But even in them the mental disorganization is gradual in development and spread over a longer or shorter period, and appears sometimes a very long interval after settlement. But no one can forecast in advance of the happening that an individual with a low mental vitality will, on meeting hardship and adversity, of necessity become mentally deranged.

However, until definite diagnostic signs or methods be found for the detection of mental conditions, psychiatrists will continue to be at loggerheads, and many mentally defective persons will pass inspection without detection. Says a New York Supreme Court Justice: "We know that insanity is a mysterious disease, that it may exist without indications, is often cunningly concealed so as almost or altogether to baffle detection even by a specialist, or to be so occult as to cause most eminent alienists to clash as to its existence in a given instance."[6]

Acetonuria in Childhood.—R. S. Frew notes that the examination of the urine from 662 children, varying in ages from a few days to 12 years, showed acetonuria in 408—*i.e.* in 61.6 per cent. Further investigation of those 408 cases brought out the following interesting facts: (1) In the great majority of the cases a specimen obtained during the first twelve hours following admission rarely showed the presence of acetone; it usually first appeared about that time, attained its maximum about thirty-six hours after admission, and then gradually diminished, all trace being gone by the fourth day, usually. (2) The disease from which the child was suffering appeared to have little, if anything, to do with its causation. (3) Its incidence was greater the younger the child, the percentage affected showing a steady decline from the youngest to the oldest child. (4) On the administration of dextrose it rapidly disappeared, and was completely gone within twelve hours.—*Proceedings of the Royal Society of Medicine.*

CALORIC FEEDING IN TUBERCULOSIS.

A STUDY OF THE EFFICIENCY OF THE DIETARY AT THE BOAT CAMP "WESTFIELD."

By N. GILBERT SEYMOUR, A.B., M.D.,

NEW YORK.

ATTENDING PHYSICIAN GOUVERNEUR HOSPITAL TUBERCULOSIS CLINIC AND ST. GEORGE'S CHURCH TUBERCULOSIS CLASS.

The therapeutic agencies for the treatment of tuberculosis at the command of a city dispensary have notably grown in variety and effectiveness during the past few years. The hospital and sanatorium facilities for the treatment of all stages of the disease, while still desperately inadequate to the problem in the larger cities, have been greatly increased, and more provision for the care of the consumptive poor is constantly being planned. Despite this progress, we are still confronted with the necessity of treating the great majority of our dispensary patients in their homes, and in New York—with its congested tenement districts and large foreign population—this means the attempt to treat tuberculosis in an environment totally unsuitable, in most instances, to the application of the cardinal principles of treatment—rest, fresh air, and proper food.

Until the sanatoria and hospitals are equal to the demand—an ideal which may not be realized in many years—the tuberculosis dispensaries must meet the problem of home treatment as best they can. One of the most successful experiments in this home treatment, as applied in New York City, has been the employment of day and night camps for the treatment of ambulant cases. I have elsewhere reported on the general effectiveness of this method of treatment, and the routine established in the several camps now conducted by different organizations.*

The most practical means yet devised of establishing day and night camps in connection with our city hospital clinics has been through the employment of old ferry-boats condemned for active service and renovated for this new use. Three such floating camps are now in service.

The present study, prepared in connection with a report on the work of the Gouverneur Hospital Tuberculosis Clinic, is concerned solely with one feature of the day camp problem as it has arisen on our own Boat Camp, the "Westfield." This feature is the question of diet, and it is one of the most practical problems which has confronted us in connection with the maintenance of our day and night camp.

In a camp with a capacity of one hundred or more patients by day and forty at night, exclusive of nurses and helpers, the food problem is not only of importance from the financial standpoint, but is also a matter of great interest and value in the scientific care of our cases.

During the five months in which the Boat Camp was wholly in charge of the Auxiliary†—that is from July to November, 1908—no attempt was made to provide regular meals for the patients in attendance. The Night Camp had not then been established.‡ The average daily attendance was twenty-

*"The Use of Day Camps and Night Camps in the Home Treatment of Tuberculosis in New York City," MEDICAL RECORD, Sept. 3, 1910.

†The Women's Auxiliary to Gouverneur Tuberculosis Clinic.

‡The first attempt at a night camp was initiated during this first season, nine of the men patients being provided by the auxiliary with cots and bedding and allowed to sleep on the boat.

five patients. A nurse from the Department of Health was in charge. The food supplied consisted of milk and eggs; bread and butter; coffee, cocoa, or tea occasionally; and a considerable quantity of fruit donated at intervals. An average of 30 quarts of milk and 8¾ dozen eggs a day was used. As there was no kitchen equipment at that time, no attempt to serve cooked meals could be made. The very irregular attendance of some of the earliest patients, and our inadequate facilities for detailed records, make it impossible to estimate, even approximately, the average food consumption of individual cases. Two quarts of milk and four eggs were provided daily for each patient, but the patients were supposed to be getting the bulk of their feeding in their own homes.

With the assumption of the control of the boat by the hospital authorities, it became possible to build and equip a model kitchen and to maintain a sufficient staff of helpers to prepare and serve at least one adequate cooked meal for the day patients. The provisions supplied for this purpose were sufficient to provide additional lighter meals for the patients attending Night Camp and for those spending both day and night upon the boat.

It was our intention, from the first, to make these meals and additional feedings conform, so far as possible, with the best and most recent work on the caloric value of the diet in the treatment of tuberculosis; but we were at once confronted with two difficulties, the economic and the racial. Most of the foods of high caloric value which are usually counted upon to raise the fuel coefficient of the diet —such foods as cream, butter, bacon, oil, and eggs —are too expensive for frequent or prolonged use in a city institution deriving its support from public funds. Furthermore, our patients are chiefly Jewish, and their religious prejudice prevents the use of bacon in any form, butter at the same meal with meat, and certain other foods of high caloric efficiency. Unlike the Italians, they are not fond of salads nor of oil, and they eat macaroni sparingly. With limited funds available for the purpose, and dealing with a class of patients trained to definite and rigid habits in their choice of food, we have not been able, as yet, to devise a dietary satisfactorily adapted to the treatment of tuberculosis; but a study of the actual food values of the present dietary is not without interest, and we aim to increase its caloric efficiency to the highest possible point under existing conditions.

TABLE I.

TOTAL EXPENDITURE IN CALORIES OF AVERAGE MAN AT REST.*

	Calories
Radiation from the body of an average man, clothed	1,536
Latent heat due to evaporation of about 1,100 gm. water from the skin and lungs	611
Heating of the expired air	80
Heating of food and drinking water taken cold and raised to body temperature: heat lost by urine and feces, total	53
Work performed by heart and respiratory muscles, plus other internal and exterior actions necessary to the maintenance of the organism, even at rest	150
Total expenditure of heat and energy—calories	2,430

*Gautier: "Diet and Dietetics." Rice-Oxley translation.

It has been estimated that a normal (healthy) man requires, while at rest, about 33 calories per kilo of body weight each day (Krohl: "Principles of Clinical Pathology." Howlett translation.) For a man of average weight (say 70 kilos, or approximately, 150 pounds) this represents a daily requirement, in food value, of 2,310 calories; and this not to increase his weight, but merely to maintain an equilibrium between food intake and bodily waste. To express it in terms of expenditure of heat and bodily energy, it has been estimated that the number of calories lost directly, or corresponding to a slight expenditure in the form of work (energy), of a man at rest, is as shown in Table I.

This total (2,430 calories) expenditure approximately balances the required value of food consumed (2,310 calories) in order to maintain the body equilibrium, or in other words, to prevent loss of flesh. It must be remembered, however, that these figures represent a man of average weight, at rest and in health. In dealing with disease, especially with febrile or wasting diseases like typhoid or tuberculosis, a certain additional percentage of fuel is necessary in order to meet the febrile increase in heat production. In typhoid fever, this necessary increase has been estimated at 25 per cent. for the average patient; that is, 41 calories per kilo of body weight per day, or approximately 3,000 calories a day, as the minimum requirement for a man weighing 150 pounds. (Coleman: "Diet in Typhoid Fever." *Journal A. M. A.*, October 9, 1909.) This is estimated to be the minimum requirement, and typhoid dietaries representing 4,000 to 6,000 calories and over have been used with excellent results.

The problem of increasing the caloric value of the food in the treatment of tuberculosis has been the subject of much study and experimentation within the past few years. Careful investigation of the effect of special dietaries based upon the principles of high caloric efficiency have been made in selected cases, or groups of cases, in many of the sanatoria; and elaborate diet lists and tables of results have been published. These investigations and their accompanying results have led no less an authority than Professor Irving Fisher to conclude that excessive diets are not necessary for satisfactory gains in weight with tuberculosis patients. He states: "Given proper foods and proper proportions of food elements, the average tuberculosis patient can be successfully nourished on 3,000 calories per day. In other words, on no more than is usually consumed by the ordinary sedentary man. . . . Weight-gaining which is purchased at the cost of strain on the physiological machinery does not mean permanent benefit." (Fisher: "Diet in Tuberculosis." Proc. Sixth Internat. Cong. Vol. I, Pt. 2.)

In an institution as small, relatively, as our Boat Camp, and so entirely under control, it seemed at first thought a comparatively simple matter to arrange a dietary upon the caloric basis or, at least, to estimate the exact caloric value of the food used. The latter investigation is logically the first to be undertaken, as it is evident that only after an estimate of the value of the existing dietary had been made could modifications be rationally introduced. Such an estimate was therefore undertaken, but it soon became apparent that no average diet could be estimated for the individual patients, both because of racial differences, with corresponding variations in diet, and because of irregularity of attendance. Furthermore, it proved to be very difficult to estimate accurately the daily consumption of all kinds of food. For example, the suet used for puddings is of the highest caloric value, but it was not used daily and the quantity used on different days varied in accordance with the number of patients in attendance on each occasion. A practical plan for a reasonably accurate estimate of the existing

dietary was finally suggested in the course of discussion at staff meeting.* This plan consisted in selecting one month, of fair average attendance, and having all provisions carefully estimated at the beginning and end of that period. As all supplies and provisions are sent to the camp in quantity on requisition from Bellevue, the difference between the amount on hand the first day of the month plus all food requisitions during the month, and the amount on hand the first day of the month following, obviously represents the total quantity of food used during the stated period. We selected the month of July, 1910, for the estimate, and the list of foods used during that period, with the exact quantities, was prepared by the senior boat nurse. By reference to standard tables of calories, the total value of these foods in the quantities used was next estimated. This is shown in the following table:

TABLE II.

FOOD USED ON BOAT CAMP "WESTFIELD" DURING THE MONTH OF JULY, 1910, WITH ESTIMATION OF THE CALORIC VALUES.*

	Pounds	Calories Per Pound	Total Calories
Milk (whole), 2,790 quarts	5,580	325	1,813,500
Eggs (raw), 930 dozens	1,511.25	720	1,088,100
Beef	865	1,460	1,262,900
Bread	496	1,395	691,920
Sugar (cane)	350	1,820	637,000
Potatoes	1,260	375	472,500
Soup meat (average beef)	390	982	382,980
Butter	77	3,615	278,355
Chopped meat (average beef)	135	982	132,570
Veal	150	580	87,000
Prunes	56	1,400	78,400
Fish (general average fresh fish)	250	300	75,000
Fat for puddings	20	3,770	71,400
Carrots (like parsnips)	210	230	48,300
Rice	21	1,630	34,230
Onions	140	225	31,500
Macaroni	16	1,665	26,640
Cabbage	170	155	26,350
Barley	11	1,800	19,800
Beets	100	185	18,500
Apples, dried (edible portion)	54	290	15,660
Hominy (like barley)	8	1,800	14,400
Beans	38	360	13,680
Farina	7	1,700	11,900
Peaches (canned)	58.5	190	11,115
Oatmeal	5.5	1,860	10,230
Peas	40	255	10,200
Apricots (canned)	12.5	460	5,750
Tomatoes (canned)	64	80	5,120
Raisins	4	440	1,760
Total calories in food used (31 days)			7,376,760

Lusk:—"Elements of the Science of Nutrition," 1909.
Thompson:—"Dietetics." Last Edition.

In the foregoing table, the foods are arranged in the order of the number of calories contributed to the total diet for the month; but it is at once apparent that this is not the order of greatest caloric efficiency. For example, the fat (suet or lard) used in the puddings has the highest food value (in calories) of any in the list (3,570 C. per pound), yet it does not head the diet because of the comparatively small amount (20 pounds) used. A more striking example—since pure fat can be used in any diet only in limited quantities—is furnished by the cereals. Thus, oatmeal has a caloric value (1,860 per pound), greater than cane sugar (1,820 C. per pound), yet it contributed but little to our totals because the amount used (5½ pounds) was so insignificant.* Macaroni is another example of a food of high value relatively little used. Oil and bacon are altogether absent from our list of available foods.

*There might have been some difference in the totals if a winter month had been selected; but, on the other hand, the average attendance is greater in July than, for instance, in January, and the variety of foods supplied is about the same.

Since the total amount of food used at the Boat Camp during July (1910) represented a fuel value of 7,376,760 calories for 31 days—or 237,960 calories per day—it remains to estimate the average caloric value of this diet for the individual patient.

*This very practical suggestion was made by the chairman of the Women's Auxiliary, Mrs. Mandel, who has taken the keenest interest in the preparation of this report.

The total attendance at the camp during the month selected was 2,456. The average daily attendance was 81. There were 24 patients at the Night Camp. It should be remembered that the food was served as a noon meal to all patients attending Day Camp, with extra nourishment—consisting of bread and butter, milk, and two eggs for each patient—at 11 A.M. and 4 P.M. A breakfast of cocoa or coffee, bread and butter, eggs, milk, and cereal was provided for the Night Camp patients or those in attendance both day and night. Bread and milk was also given out in the evening when there was any surplus. It is apparent that these morning and evening meals must be deducted from the general estimate, since the Night Camp patients received the greater part of their food elsewhere. The breakfast, estimated approximately at 672 calories, and the evening nourishment 272 calories (see Tables III and IV), together represent 944 calories used for each Night Camp patient, or a total of 22,656 calories per day. This reduces the total estimate to 215,304 calories per day; and this, among 81 patients (the average daily attendance), represents an average per patient of 2,658 calories per day. If this average were accurate in the individual case it would satisfy the dietetic requirements at the camp, we think, since these patients were getting two meals a day in their own homes and in the majority of instances two home meals would certainly suffice to raise the total calories to 3,000 per day, or over; but the estimate is necessarily only approximate, and certain inaccuracies are apparent. Thus, while the average daily attendance was 81, yet the individuals counted were not always the same patients, some dropping out or attending irregularly and others taking their place. Again, while the average value of the food used daily is easily estimated, not all the patients were eating the same quantities or the same variety. Because of individual variations in appetite and personal idiosyncrasy, as well as for the foregoing reasons, some patients were doubtless getting more than the necessary amount of food (or the estimated caloric requirement), and others less. Furthermore, children were estimated with the adults, although they had more milk, proportionately, and less of other foods.

An effort to make the individual estimate more exact by working out the caloric value of separate meals was rendered difficult by the necessary variation in the principal (noon) meal from day to day. The following tables are therefore approximate only:

TABLE III.

CALORIC VALUE OF AVERAGE DAILY DIET ESTIMATED FOR INDIVIDUAL PATIENT.*

BREAKFAST	Calories
Coffee or cocoa, 1 cup (value of the contained milk and sugar only)	50
Bread, 2 slices	132
Eggs, 2	150
Milk, 1 cup (7 ounces)	140
Cereal, 1 standard portion	100
Butter, 1 standard portion	100
Total, calories	672

A.M. NOURISHMENT—11 A.M.	Calories
Bread, 2 slices	132
Butter, standard portion	100
Milk, 7 ounces	140
Eggs, 2	150
Total, calories	522

*These estimates are based upon a table of the approximate caloric values of "standard portions" (equal to 100 calories each) which was worked out by a New York Hospital nurse, Miss F. M. Johnson, and quoted in the *American Journal of Nursing*, Vol. X. No. 7 (April, 1910).

NOON MEAL

	Calories
Soup (vegetable), estimated	50
Meat (or fish), one portion	100
Potatoes (1), baked or boiled	100
Parsnips or carrots	50
Bread, 2 slices	132
Stewed fruit, one portion	100
Tea (with sugar)	33
(Or milk, 7 ounces, for the children—140 calories)	
Total, calories*	565
Total (children), calories	672

P.M. NOURISHMENT—4 P.M.

	Calories
Same as A.M. nourishment	522

*The total calories used in the noon meal is obviously underestimated in this table, as will be seen by a comparison with the table of total quantities of foods used during the month. The majority of the different foods there listed were used at the noon meal, and the meal estimated above represents a minimum both in variety and in caloric value. To this fact is due the apparent discrepancy between the estimate of the diet by daily average and by average meals. The former (2,658 calories per patient per day) is more accurate than the latter (1,609 calories—as above).

TABLE IV.

TOTALS—ESTIMATED BY MEALS.

	Adults (Day) Calories	Adults (Night) Calories	Adults (D. & N.) Calories	Children Calories
Breakfast	....	672	672	.....
A.M. nourishment	522	...	522	522
Noon meal	565	...	565	672
P.M. nourishment	522	...	522	522
Night lunch	.....	272	272	.....
Milk....140 C.	.....	...	.....	.....
Bread....132	.....	...	.....	.....
272	.....	...	.....	.....
Total Calories	1,609 Plus 2 home meals	944 Plus 2 home meals	2,553 Plus 1 home meal	1,716 Plus 2 home meals

In these estimates, also, no account could be taken of individual variations in diet, and the children were estimated with the adults although their diet was higher in food values and lower in quantity. It should be noted again that no cream, bacon, or salad oil was used in this dietary, and that butter could not be used at the same meal with meat.

From the foregoing study of the dietary at our Boat Camp it may be concluded that with a fair variety of ordinary foods, and with no attempt to employ special diets or forced feeding—other than the extra nourishments morning and afternoon, and an abundant supply of milk and eggs—a fairly high average of caloric value has been attained. But considering the average home conditions of our patients, most of whom come to us ill-nourished, we believe that this dietary could be raised to 3,000 calories or more daily with advantage to the majority of those attending the camp regularly or living there. To accomplish this would require not so much a change of foods as the more frequent use of those of higher value—such as cereals, macaroni, prunes, bread, and certain stewed fruits—in place of bulkier foods of fewer calories, as potatoes, tomatoes, onions, cabbage, etc. It might be possible also to encourage a more liberal use of butter at all meals except dinner, and to introduce lactose in place of cane sugar.

To estimate the diet of the individual patient with absolute accuracy, or to adapt the diet exactly to the needs of the individual—a procedure which involves the exact measurement of all foods consumed daily by each patient—has been impossible heretofore because of the inadequate number of assistants trained for such work and because of the lack of patients with sufficient intelligence to cooperate in such an undertaking. It is our purpose, however, to work gradually toward that ideal by the selection at first of a few of the more intelligent and trustworthy of our patients—such as those already selected for the "intensive" or "class" treatment—for special diets which they will be taught to estimate with accuracy and enter for us upon their daily records. With such a beginning, a gradual modification of the entire dietary can be effected in time, and the individual patient receive that personal attention, adapted to his individual needs, which is the ideal of all treatment.

129 East Seventeenth Street.

TUBERCULOSIS OF THE BRAIN;

REPORT OF A CASE OF TUBERCLE OF THE LEFT OPTIC THALAMUS.

By J. L. POMEROY, M.D.,

MONROVIA, CAL.

The following case of a solitary tubercle of the optic thalamus deserves to be recorded, not only because of the rarity of such a lesion, but also because of the peculiar symptoms. The patient was under my observation and exclusive care, hence the records throughout are the results of daily notes. It is regretted that the tests for sensory changes and for hemianopsia were inconclusive owing to the mental symptoms. The patient fell under my care while resident physician at Riverside Hospital Sanatorium, New York City, during the fall of 1908.

A. F.—Father is alive, 64 years old, in good health; not alcoholic; occupation, laborer; mother died thirteen years ago, cause unknown. There is no history of cancer or insanity. There are four brothers and two sisters living; all are well. One brother died of typhoid fever. One sister died of tuberculosis at the age of 21.

Nothing is known of the patient's early childhood. He is the fourth child; was born in Faversham, England, and his mother used to fear that his lungs were weak. The patient is 30 years of age; has had no serious illness, and received little schooling. He left home at the age of twelve and did odd jobs in London until eighteen. At the age of 18 years he was a fireman. His early habits were good. He denies the excessive use of alcohol and contracted no venereal diseases. He married at twenty; was earning thirty-six shillings a week. His disposition was somewhat stubborn, but usually quiet and self-controlled. His habits were regular; he was always at work. He never received any injuries, but had two operations for varicose veins of the leg when about twenty-three.

He came to the United States six years ago; worked as a motorman four months, when he went back and got his wife, and returned with her. There are two healthy children; one seven years old, the other four, both girls. The wife seems healthy. She has been working as a janitress since the husband became ill. There is no history of miscarriages. The patient has life insurance in the "Prudential." Pays fifteen cents a week; has had it for three years.

Four years ago patient had a severe hemorrhage (hemoptysis) and was compelled to give up his work as motorman. He attended the Post-Graduate Clinic, realized what his disease was, but gradually lost weight and strength. He finally became so weak that he was taken to Bellevue Hospital and transferred here (Riverside Hospital) August 11. In July he suffered severely from diarrhea; also he went to the Harlem Hospital to have his

right ear examined on account of buzzing. The doctor could not do anything for him. There was no discharge nor symptoms of inflammation. Shortly afterward he complained of dizziness and his wife noticed that he showed slight mistakes in memory. He would tell the children to be quiet; then in a few minutes would ask them why they were so quiet. There is no history of swelling of the feet, no headache, no convulsions, or eye trouble of a serious nature. Once an electric fuse blew out and scorched his eyes, but it was not serious.

No particular symptoms were noted until August 26, when he was found in bed suffering from vertigo; his temperature was 99° F, pulse 110, respiration 22, coughed badly, very emaciated, gait unsteady, expression staring and blank; his skin shows no scars. There was a marked Romberg's sign; his reflexes were all normal, the knee jerks perhaps a little lively but equal; the right pupil was a little larger than the left and did not react as well

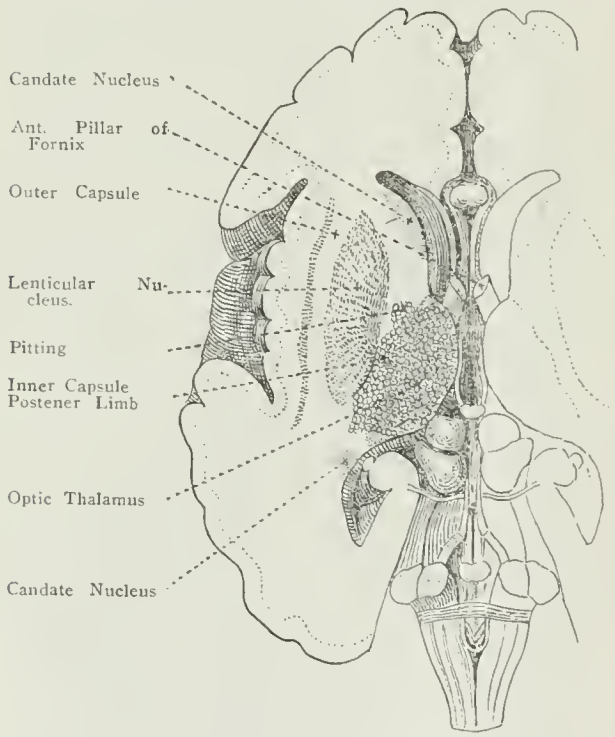

Fig. 1.—Location of the tumor in a case of tubercle of the brain; left optic thalamus (schematic).

for light. His left nasolabial furrow was a little deeper than the right. There was no tremor of tongue or face; his hands were slightly tremulous; there were no changes in sensation. At times one noticed a little nystagmus.

Ears.—Hearing normal; watch heard at thirty inches; drum membranes normal.

Eyes.—The opthalmoscope shows reddening of both discs, and a little blurring of the outlines.

Lungs.—Marked infiltration through both upper lobes; scattered râles at the bases. Signs of cavity formation at right apex.

Heart sounds feeble, apex in sixth interspace; no murmur.

Urine.—Specific gravity, 1015; reaction, acid; color, cloudy straw; amount in twenty-four hours, 32 oz.; sugar, negative. There was a very large amount of albumin and microscopic examination showed many hyaline and granular casts, no pus cells.

Abdomen.—Slight tenderness over the epigastrium; liver dullness extends about 4 inches below the midsternal edge.

Extremities.—The muscles of the calves are much emaciated, but there is fair muscular power.

Mental Condition.—The patient goes to his meals regularly and shows nothing queer in his actions in the ward. His movements are a little slow and uncertain. He sleeps well and he does not show much confusion as to his surroundings.

Orientation.—What month is this? I don't know. I feel a little upset, perhaps *personally* I could tell you right away you know it is not; isn't." He gives the time of day, but calls it correctly at one time; then incorrectly at another. He knows he is in a hospital, but cannot name it; thinks he can get away by train; New York City is about two miles away. He recognizes doctors and nurses, but does not remember their names.

Memory.—This was gone over with his wife, who was able to point out deficiencies. He cannot remember how long he has been in the hospital, says three weeks (two weeks); states that he went to a hospital three weeks ago to have his ears examined, but wife says it was in June. Gave his age correctly (30 years), where he was born, and the date, August 12, and yet he could not tell when his last birthday was, and could not give the month of the year (which was August). He could not tell his occupation, his wife's name, nor his children's names, but he recognized them when they were given him. He could not give either his father's or mother's name, nor could he remember his sister' or brothers' names until his wife prompted him. Also he failed to give any connected history of his life; could not remember what steamboat he came over on; knew that he came over here six years ago; that he worked for the Met. R.R.

He would hesitate a long time over a question, often expressed feeling of inadequacy, and occasionally showed perseveration. Called wife "Sis," which was not habitual. Is your appetite good? "My appetite has been good; once or twice it has been rather *dizzy*, you know." Which child were you? "That was the fourth child born." Which child? "That child." What do you mean? "Why, the fourth, Fred, Alf, George—that's all." That's only three. "That's what I'm saying." What hospital is this? "This is a funny; I can't never think of the hospital. It's St. Luke's." Where is St. Luke's? "Up to the Union." What do you mean? "Why, up to the Union." I don't understand. "It ain't no funny kind of a place. It's just an ordinary place like any other hospital." You mean it belongs to the Union? "Yes, but it may not now; you have got it under another name. It doesn't amount to the same name." How do you get there? "I'm saying Union; it ain't the Union at all; it's up to the Grove." Where? "The Railway Grove up Waller Row." What do you mean? "The place they call it I don't know anything else."

He named and picked out a number of articles readily. Knew their uses; understood mewing of a cat, barking of a dog, watch tick, whistling, intonation of voice, scolding, etc.

Alphabet? A, B, C, D, E, F, G, H, I—L, K, that's all. Numerals? Counts from 1 to 20 correctly. Lord's prayer? Can't remember. Months of the year? Correct up to August. Knew Christmas was in December, but did not know what month Thanksgiving Day was in.

Adding.—8 and 11=don't know; 3 and 5=8; 12 and 6=don't know.

Spelling.—New York City, O. K. Brooklyn, O. K. Cincinnati, Cin-cin-cin-nat-nat—. Buffalo, Buf-buf—.

Named days of the week correctly. Named colors correctly. Called meaning of Y. M. C. A., U. S. A., O. K. Identified sweet, sour, salt, and bitter. Gave number of syllables in hospital, dog, but stumbled on Brooklyn.

Emotional Tone.—Generally quiet in his reactions. No inadequate reactions. Cries a little while being examined with wife by his side, and could not explain it. No bizarre reactions.

No Hallucinations but Peculiar Distortions of Vision.—States that when he is lying down the clock on the wall seems to project from the wall about six inches. This disappears when he gets up. He can read well from print, but it takes time and he stumbles a little. He is right handed. He makes no use of gestures, occasionally shows impatience, has good insight. He expresses his difficulty in this way: "I'm all mixed up. I can't think of it. I've got it on my tongue (beats with hand on chair). Oh, dear, dear. I'm all right in my head, I can tell you everything only I get mixed up. I'm just getting forgetful. I can think of everything but I can't spit it out." His speech is clear, he gives the test phrases well. There is no scanning. No repetitions. There is nothing particular in his handwriting.

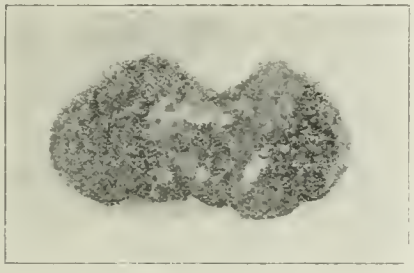

Fig. 2—Solitary tubercle of the brain.

The patient copied drawings fairly well. In writing to his wife his efforts were only partly successful. He addressed her as "Dear Sis," and frequently omitted words and wrote the wrong address. Patient could walk fairly well, but was awkward.

The diagnosis of brain tumor, tuberculous in nature, seemed certain. The exact location was uncertain, in closely reviewing the symptoms, the lack of facial expression, with marked emotional disturbance, the rather smooth right face, the awkward movements, tremulous hands, together with the negative data for other lesions of the brain suggested a thalamus lesion. The classical symptoms (if there are any) on account of his mental condition could not be demonstrated. (Sensory changes and homonymous hemianopia.) Therefore the diagnosis as to exact localization was somewhat uncertain.

The bedside notes of this case showed that on August 30 there was no Balbinski, the cremaster and abdominal reflexes were good, elbow jerks normal. No changes so far as could be determined in sensation. Patient continued unduly emotional, crying a great deal without apparent cause. On being questioned couldn't explain this. There was never any motor aphasia. He never showed any spontaneous speech, and sank gradually into a semi-comatose condition. Never showed any hallucinations or delusions. He gradually sank into coma and died about three months from onset of his first symptoms. Permission for postmortem was obtained only for the brain. Autopsy report follows, with photograph of the tumor and schematic drawing of its localization.

Postmortem Report.—On opening skull there was some thickening of dura. The pia was adherent over both lateral surfaces, over the Rolandic area especially there were white plaques and dense adhesions. The left side of the brain seemed a little fuller than the right. Edema was marked. On opening the lateral ventricles a tumor mass presented itself, in the left optic thalamus. The tip was somewhat translucent, the choroid plexus adherent. Slightly anterior was a pitting and depression. The tumor arises from the region of the optic thalamus, projects internally and a little over the median line. It is a grayish white with dark areas over the surface, at the top in the median line is a semi-translucent area, where the choroid was adherent. A circular pitting about two cm. in diameter and deep lies to the interior outer margin, toward the caudate nucleus. The opposite thalamus is normal. The mass contains hard nodules, though soft in spots. It is embedded in the thalamus. Histological and biological examination showed this tumor to be tuberculous.

In general one can say that organic lesions in the central nervous system occur in pulmonary tuberculosis rather seldom. In some instances there seems to be a locus minoris resistentiæ for brain infection. In other instances actual entrance of large quantities of infectious material is the determining factor, whilst trauma, mental fatigue or mental stress, alcohol, and syphilis all play an etiological rôle.

Solitary tubercle deposits in the brain substance are also rare in phthisis. Kamboseff found in 900 autopsies only twice tuberculous plaques in the temporal lobes, and once a solitary tubercle in left corpus striatum. Greiwe describes a case of a solitary tubercle in the right tegmentum, in a phthisical patient, with paralysis of the left arm and leg. Microscopical examination showed tubercle bacilli in the wall on an artery which ran to the tumor, with degeneration in the tegmentum, the corpora quadrigemina, and the fillet. Putawski reports an almost similar case. Solitary tubercle in the brain may be almost symptomless.

Schlesinger describes a case of central cord tuberculosis in the upper cervical region in a severely diseased tubercular individual. The nerve nuclei and connected nerve fibers were normal. On the side of the lesion, however, from the cervical segment involved in the middle dorsal segment there was descending degeneration. Clinically, there was marked unilateral muscular atrophy of the upper extremity, then rapidly paralysis appeared on the other side with disturbance of sensation, temperature sense and pain sensibility becoming obliterated. The patient died from paralysis of the diaphragm. Bristowe reports a case in which at autopsy there was a recent tubercle in the pons, and an old fibroid encapsulated mass in the cerebellum which was entirely symptomless.

A peculiar form of irritation of the spinal cord is described by Levy and Follet; in lung tuberculosis with cavity formation, in 50 cases they found marked ankle clonus nine times. These patients were neurotic individuals, and the authors thought

that the toxin caused some irritation of the pyramidal tracts of the cord. Leimbach reports a case of tubercle of the cerebellum (Wurm). Tuberculous tumors in the cord are seldom found and may be entirely symptomless. They occur mainly in generalized tuberculosis. As a rule localizing symptoms soon develop one-sided weakness and paralysis. Secondary degeneration is not common, as the condition usually terminates in a short time. Sudeck describes the case of a man 34 years of age who had suffered for two years with tuberculosis of the larynx and lung, began to have pain in left leg, later paralysis of both legs, cystitis, and decubitis. The section showed in the lumbar and lower dorsal area tubercle with typical ascending degeneration. Von Le Boeuf describes a tubercle of the medulla oblongata about the size of a small nut with right sided pain and paralysis of the body but no secondary degeneration in the nervous systems. Sachs describes a case in which clinically symptoms of spinal cord tubercle appeared first before the lung symptoms. At autopsy, however, it seems that the lung tuberculosis was only latent, as there was an old cavity and fibrous thickenings of not recent development. P. Foa found in a child who had died of nephritis, an old tubercle in the cerebellum which was practically healed. Some years prior to death, he had at one time had symptoms of meningeal irritation. Gierlich reports a case of tubercle of the brain substance.

In conclusion it may be stated that solitary tubercle of the brain substance, uncomplicated by meningitis is a rarity in pulmonary tuberculosis. In nearly all cases the tumors are multiple or show also meningeal infection. In the case here reported there were no evidences of meningeal involvement nor any tubercles in the other parts of the brain. It is further noteworthy that the lesion in the optic thalamus gave rise mainly to mental symptoms, emotional disturbances, certain aphasic difficulties and few classical symptoms of the "syndrome thalamique." Further there was never any vomiting, headache, convulsions, paralysis or other marked motor symptoms.

SAFETY AND SCIENCE IN NITROUS OXIDE ADMINISTRATION.

By RAYMOND C. COBURN, M.A., M.D.,

NEW YORK.

In the Medical Record, May 4, 1912, I outlined "A Scientific System of Administering Ether." This is intended as a companion article, dealing with the same phase of nitrous oxide administration. As will be subsequently shown some of the principles involved in the administration of nitrous oxide and of ether are identical and include a separate and pliable control of oxygen and of rebreathing, sterilization of all parts contaminated by rebreathing, and locating the rebreathing bag close to the patient's face. Constant and even flow of gases, pressure-reducing valves, percentages gauges, positive pressure, etc., which at present are being so highly lauded, especially by those interested in the manufacture and sale of these expensive appliances, are not only unnecessary, but may be productive of actual harm, as will be later shown.

As is the case with ether, nitrous oxide is administered through inhalation by one of two general systems: (1) without rebreathing; (2) with rebreathing, or by various modifications of these two systems.* With rebreathing the flow of gases may be constant or intermittent, while without rebreathing the flow should be constant.

In the administration of nitrous oxide one of the first questions to decide is whether it shall be administered with or without rebreathing. Is it scientific to administer it with rebreathing or is rebreathing used simply to lessen the cost? After an extensive experience with both systems of administering nitrous oxide in major surgery it is the firm belief of the writer that rebreathing nitrous oxide is scientific and adds an element of safety to this form of anesthesia. Henderson, with his remarkable work on carbon dioxide, has practically revolutionized the science of administering anesthetics, and no longer can rebreathing be considered a mere matter of dollars and cents.

In normal life the amount of air respired is usually placed at 500 c.c., which at 18 respirations per minute gives a total of about 140 gallons of air respired per hour. In physiological amounts nitrous oxide exerts a "respiratory stimulant" action. In its prolonged administration without rebreathing the amount of respired gases averages 250 gallons per hour. Teter places it at 270 gallons per hour. With a respiration nearly double the normal it is evident that this pronounced overventilation of the lungs markedly lowers the carbon dioxide content of the blood. If Henderson's theory of acapnia being one of the causative factors of shock is correct, and it seems to me that no one who has had experience with both systems of administration, using the proper technic in rebreathing, can doubt it, then there is an absolute and scientific demand for rebreathing in the prolonged administration of nitrous oxide in order to avoid the production of acapnia. Of course, it is recognized that rebreathing is not the only source of the requisite carbon dioxide, as this gas can be administered pure and the same beneficial results follow.

*With ether the names usually given to these systems are the open and the closed, meaning thereby without rebreathing and with rebreathing. In a forthcoming article in the Reference Handbook of the Medical Sciences, Vol. I, I show that the semi-open system, as defined by Hewitt, is impossible of attainment, and that the so-called semi-open system is a modification of the closed system.

but this unnecessarily complicates the administration, and, generally speaking, it is not so practical. In this article, then, the term rebreathing is used in the broader significance of furnishing carbon dioxide.

Henderson[1] says: "Ether in quantities short of profound anesthesia exerts a 'respiratory stimulant' influence which lowers the threshold for carbon dioxide and thus tends to induce acapnia." Nitrous oxide apparently acts in the same manner, only in a more pronounced degree, as the pulmonary ventilation under this agent is about double the normal. This excessive pulmonary ventilation under nitrous oxide is not a theory; it is a fact. The exact amount of nitrous oxide and oxygen used can be easily and accurately determined, and while this amount varies in individual cases it always greatly exceeds the normal amount of air respired. If the acapnial theory is correct the demand for rebreathing in the administration of nitrous oxide is positive and unequivocal, and clinical results clearly support this contention.

Some affirm that before the prevalence of rebreathing in the administration of nitrous oxide there were many reports that there was less shock with this agent than with the other anesthetics, and this is undoubtedly true. This is due to the fact that nitrous oxide, regardless of the method of administration, causes less shock than the other anesthetics. Crile[2] says that under nitrous oxide trauma causes only one-fourth the pathological lesions of the brain cells that occur under ether. In other words, aside from hemorrhage, surgical shock, as to cause and prevention, is chiefly anesthetic, local, and general. Since, then, in the administration of nitrous oxide it is necessary to employ rebreathing to prevent acapnia, the rebreathing itself must be under pliable control so as to fulfill adequately the constantly varying requirements. It is not sufficient that there be simply rebreathing; it must be possible to increase or decrease the amount of rebreathing according to the indications. Where the flow of the gases is continuous it is impossible to increase the rebreathing beyond a certain low limit. After considerable experience with an apparatus that provided for a constant flow, I found it required an average of 125 gallons of nitrous oxide and oxygen per hour, and the rebreathing could not be practically increased beyond this amount, and that, especially in abdominal operations lasting from two to three hours, the blood pressure would become quite low and respiration shallow. Since the advent of rebreathing in nitrous oxide, which is based upon Henderson's nitrous oxide administration, which is based upon Henderson's theory of the physiological action of carbon dioxide, I have used an apparatus in which the flow is intermittent and the rebreathing bag is close to the patient's face. I am now able to increase or decrease the rebreathing at will, and in this manner quite effectually control respiration and blood pressure, except in cases of low resistance or hemorrhage, and in these cases, after the normal saline infusion is given intravenously, the blood pressure does not usually fall again as it does when the carbon dioxide retention is not properly controlled. The explanation of this difference is easily given: in acapnia the fall in blood pressure is due to a dilatation of the venous system, and when the saline infusion is given the blood pressure is usually soon markedly increased and falls again as the venous system further dilates, whereas with a proper retention of carbon dioxide the fall in the blood pressure is due chiefly to a loss in the volume of the blood, and when the saline infusion is given, the volume of the circulating fluid being restored, the blood pressure is likewise improved, and, as the carbon dioxide retention maintains venous tonus, it thereby maintains the increased blood pressure. In other words, in cases of carbon dioxide retention the beneficial effects of the saline infusion are much more permanent than in cases of acapnia.

Another practical point I have learned in the administration of nitrous oxide with rebreathing under pliable control; in abdominal operations, with the peritoneum open, the patient will tolerate to good advantage double the amount of rebreathing that the same patient will tolerate when the peritoneum is closed and there is little exposure of the capillaries. This I believe is due to the fact that carbon dioxide, being a diffusible gas, rapidly transpires through the thin walls of the capillaries into the air whenever there is considerable exposure of these vessels.

The death reported by Boys[3] is highly instructive in this connection. In addition to the report (q.v.) Boys kindly furnished me the following additional information in answer to my questions: "(1) The patient was frightened before and especially as the gas was turned on. He struggled so that it took the orderly and nurse to keep him on the table. It was with difficulty that the doctor finally got him under, taking perhaps fifteen minutes. (2) No preliminary hypodermic medication was used. (3) The anesthetic was administered with rebreathing. This was not begun till he was under, after which time he rebreathed the mixed gases until he showed slight cyanosis. This was not to exceed two or three minutes, after which the gases were changed and used directly for two or three minutes and the rebreathing resumed as before." Everything just mentioned in this case tended to produce acapnia: preanesthetic fear and no preliminary hypodermic; great fright "as gas was turned on"; fright and struggling during a prolonged induction; no rebreathing during the induction, or until after most, if not all, of the damage had been done. When rebreathing was used the type employed would tend to augment the acapnia already existing—two or three minutes of rebreathing, then two or three minutes without rebreathing. This intermittent rebreathing would have the same effect upon the carbon dioxide content of the blood as intermittent light and deep ether anesthesia by the open method. This death was clearly one of acapnia, and these same circumstances and conditions often cause sudden fatalities under ether as clearly shown by Henderson.[4]

The alleviation and prevention of shock is not the only benefit of rebreathing. Nitrous oxide produces a light anesthesia. The retained carbon dioxide increases the respiratory movement and thereby causes the absorption of a greater amount of the anesthetic. In this manner rebreathing deepens the anesthesia. Besides, the regularity of respiration thus secured is a great element of safety in this form of anesthesia, as it tends to prevent periods of apnea so often seen under this anesthetic. While this apnea is usually not serious it may under certain circumstances be the exciting cause of a fatality.[5] It might be interesting to state in this connection that the method of rebreathing with an intermittent flow requires, for major anesthesia, an average of 45 gallons of nitrous oxide and oxygen

per hour, and for hospitals the cost of this anesthesia, therefore, is considerably less than one dollar per hour.

The location of the rebreathing bag is an important matter: it should be close to the patient's face, just as it has always been for ether. However, on most of the specially designed apparatus for the administration of nitrous oxide the rebreathing bag is placed upon the cylinder stand, several feet from the patient. Before the development of the rebreathing method this location was proper, for then the movement was only in one direction—towards the patient's face—and the pressure in the bag relieved the patient of any respiratory work. Rebreathing has entirely changed the conditions; the movement now is in both directions. It wastes the patient's energy to breathe back and forth through a tube three or four feet long. Besides, this long tube causes an unnecessarily rapid accumulation of carbon dioxide and thereby shortens the periods of rebreathing.[6] In addition, the patient is often forced to breathe back and forth through a part of a large cylinder stand that cannot be cleansed or sterilized. This does not even fulfill the requirements of ordinary cleanliness. Sterilization is essential in the rebreathing method.

Pressure-reducing valves to insure a constant and even flow of the gases are without usefulness where the flow is intermittent, for, to fill the bag quickly, the pressure in the cylinder should not be greatly reduced. If there is a constant flow the rebreathing is not under pliable control.

Percentage gauges, giving definite mixtures of nitrous oxide and oxygen, is another favorite theme of manufacturers. The object sought is that the anesthetist may know the percentage of oxygen which the patient inhales. Do surgeons measure their incisions or anesthetists weigh their chloroform? Who knows the percentage of his ether vapor? Oxygen is used simply to maintain the proper degree of oxygenation, the indications for its use are clear, and the amount used is always "q.s," just as it is with ether, chloroform, and the surgeon's knife. Simplify and "scientificize" your apparatus; heavy and cumbersome cylinder stands are an unnecessary inconvenience; throw away your pressure-reducing valves and percentage gauges; save only one rubber bag and place it in its proper location; then administer nitrous oxide and oxygen just as you do any other anesthetic, and cease to expect the apparatus to administer this anesthetic for you!

Positive pressure, for other than thoracic surgery, is another method which is mentioned frequently, the benefit claimed is that a larger amount of nitrous oxide is thereby forced into the blood stream, and this increased amount of the anesthetic absorbed deepens the anesthesia. But does the end justify the means? Here again experience with other general anesthetics sheds considerable light upon this phase of nitrous oxide administration. At the German Hospital, New York City, there has been considerable experience in thoracic surgery with the administration of all the general anesthetics in the positive differential cabinet, as well as in the universal differential pressure chamber with negative pressure. At first, under continuous positive pressure, patients suffered from what seemed to be shock. To prevent this the pressure was released frequently so that the lungs might collapse at frequent intervals, and it was found that patients then withstood the operative procedure better. In operations under negative pressure these undesirable conditions were not experienced. In the intratracheal insufflation method of administering ether it is also considered a matter of safety to release the continuous pressure frequently, and some apparatus have automatic devices for this special purpose. In the light of this experience and practice, then, it may be said without qualification that, as advocated and practised by some anesthetists, the administration of nitrous oxide with continuous positive pressure is productive of positive harm.

A preliminary hypodermic of morphine and atropine is an essential element of safety in this form of anesthesia. Morphine, on account of its depressing effect upon respiration, should always be guarded with atropine. Apnea is much more likely to follow where morphine alone is used. The case reported by Olow[5] is instructive on this point. This case also emphasizes the practical importance of always maintaining a free and unobstructed air way. Means for securing this have been previously discussed.[7] Another important element of safety is the addition of a small amount of ether when indicated, the blood always being kept well oxygenated. Selected cases may be carried through prolonged operations without the need of any ether whatever, but to exclude ether altogether in routine cases in major anesthesia, except when supplemented by local anesthesia, is to court danger. A claim to a few hundred cases of this character,[8] without any ether or other adjuvant anesthetic whatever, adds no assurance that the procedure is safe. A "play to the gallery," whether by anesthetist or surgeon, endangers the patient.

Some critics claim that the after effect of nitrous dioxide with "just a little ether," as far as nausea and vomiting are concerned, are quite as pronounced as those following straight ether. Allen[9] cites one such case and thereby disproves his own contention, for the "exception proves the rule."

Summary.—The essentials are: preliminary hypodermic medication of morphine and atropine; pliable control of rebreathing and of oxygen throughout the administration; blood always well oxygenated; rebreathing bag close to the patient's face; sterilization of all parts contaminated by breathing; and small amounts of ether as an adjuvant anesthetic whenever indicated, or infiltration of the field with a local anesthetic. Pressure-reducing valves and percentage gauges are unnecessary. Constant flow of gases prevents pliable control of rebreathing. Continuous positive pressure is harmful.

A THERAPEUTIC RESOURCE IN HERNIA AND OTHER BOWEL OBSTRUCTIONS.

By WILLIAM FRANCIS WAUGH, A.M., M.D.,
CHICAGO.
PROFESSOR OF THERAPEUTICS, BENNETT MEDICAL COLLEGE.

The basis of the old therapeutics was exclusively empirical. We had no better reason for administering drugs than the whilom favorable results following them, and whether these were *post hoc* or *propter hoc* was generally a question, decided by the optimism or pessimism of the doctor. Our study of drugs in the scientific sense commenced when we secured pure and uniform drugs to study; for naught but uncertain and varying effects were obtainable from uncertain and varying agencies. The utilization of single remedies, chemical salts and active principles in absolute purity, with a definite knowledge of the powers of the remedy and the results following its exhibition in doses pushed to exact effect desired, has given us an armamentarium of limited extent but of priceless value. This "definite knowledge" of the remedy, like the definite knowledge of pathology afforded by the modern laboratory, enables the therapeutist to apply his drugs with an accuracy that approaches the mathematic, instead of the old methods of more or less successful guessing, approximation, measuring of possibilities, timorous "trying," and general inefficiency that so disgusted the practitioner of the past quarter century.

Familiarity with these agents inevitably breeds a confidence in their powers that can not but appear unjustifiable to the man who has not enjoyed such an experience. He who has become accustomed to the quick and radical results of mechanical methods, surgical and others, must be impatient with the slower processes of the drug user, as viewed in the light afforded by his own experience with the crude and doubtful preparations of the past. With this section of the profession the knowledge of the newer therapeutics and the brilliant achievements it makes attainable must come slowly, by demonstration and reasoning that appeals to that element, which, conservative in accepting claims, nevertheless does not wish to lose any real advance in the means of treating the sick.

About twenty years ago the European medical journals, especially those of France, recorded a number of cases in which hyoscyamine was employed to facilitate the reduction of hernias. These reports were quite favorable. A full dose of the alkaloid was administered, and the patient left in quiet until the full action of the remedy was demonstrated by dryness of the mouth, flushing of the face, dilatation of the pupils, and especially by muscular relaxation and subsidence of the tension and tenderness that offered the greatest obstacle to successful taxis. When this condition had been established and the patient was fully under the influence of the drug the hernial protrusion either was restored spontaneously or yielded to the slightest painless manipulation.

This method has been employed in America with similar success, by many practitioners. The preparation found most satisfactory was that known as amorphous hyoscyamine, the combined alkaloids of hyoscyamus. It consists of hyoscine with hyoscyamine, the former usually but not always in predominant proportions. Cushny and Peebles found that hyoscyamine differed from atropine in acting more strongly as a sedative to the vagus, and in the influence over the salivary secretion. Most of the reports upon this alkaloid are useless because the specimens employed contained a proportion of hyoscine. In practice it is not easy if possible to differentiate between atropine and hyoscyamine. I have administered many doses of each, and studied the cases clinically, without being able to detect any appreciable difference, such as would enable me to recognize which of the two might have been employed.

The effects of hyoscine are quite different. They may be readily distinguished from those of atropine, except in those cases in which the body fluids seem to possess the faculty of converting hyoscine into atropine. Then we see typical atropine symptoms follow the administration of hyoscine of known purity. These cases are not so rare as those in which the body fluids possess the property of reducing iodoform and other iodic combinations, and traces of these applied locally induce acute iodine intoxication.

At present we face a difficulty under the administration of the Pure Food and Drug Act. The Pharmacopœia does not recognize the combined or amorphous alkaloids; and the officials entrusted with the enforcement of this law object to the use of the word "hyoscyamine" except for the pure crystallized form. Amorphous hyoscyamine must be crystalline hyoscyamine—which it is not—or the seller may be liable to prosecution. The term "combined alkaloids" may be objected to, because to combine is to unite things previously separate. Some such clumsy term as "total alkaloids derived from hyoscyamus" is required; or a fanciful name devised which renders it proprietary. Otherwise the use of this remedy is illegal!

Frankly, I believe this is for the best; since the quantities and proportions of the two alkaloids vary in different specimens of the plant, and the boasted uniformity of the active principles is lost. It is better to prepare a definite mixture of the two, which may be varied as occasion demands. Experience favors the amorphous alkaloid; in which, as said, hyoscine predominates, but not always and never very decidedly. Since the relative strength of the two is about the same, I would suggest a mixture of three parts hyoscine and two parts atropine. The adult male dose of the combination should be placed at 1/100 grain. The variation in individual susceptibility to these alkaloids is very great. One of my patients is strongly affected by 1/2500 grain of hyoscine, and another exhibited toxic symptoms after taking only 1/1500 grain of atropine. The dose of 1/100 grain should therefore be divided into ten, and one part administered every five to twenty minutes until the desirable effect has been induced. The hernia may then be reduced with little if any difficulty, or pain. If, however, it is an old affair and adhesions confine the sac in its place, it is idle to suppose that any drug can succeed, and operation is to be considered.

Many of those who have thus utilized amorphous hyoscyamine have found it advisable to add strychnine. Hyoscyamine relaxes the circular fibers of the gut, while strychnine energizes the longitudinal

fibers. Waiving all *a priori* discussion of the possibility of such simultaneous antagonistic activities, clinical experience has been distinctly and uniformly favorable to the measure. About 1/250 grain of strychnine may be given with each 1/1000-grain dose of the combined atropine and hyoscine.

The man who denounces any other than surgical treatment for hernia will not favor this suggestion; but what is he to do if the patient absolutely refuses to permit operation? At all events the success of the hyoscyamine method has been so pronounced as to justify its recommendation in suitable cases.

The therapeutic dogma established, of the use of strychnine to stimulate the longitudinal or expulsive fibers of the bowel, and hyoscyamine to relax the circular fibers, its possible applications extend far beyond hernias. In fecal impactions, and the various forms of intestinal obstruction, paresis of the expulsive fibers and spasm of the circular form a factor far more frequent and important than most practitioners suppose. Many a time the use of this combination has deprived the surgeon of a fee for doing an appendectomy or other intestinal operation. In torsion this method is almost invariably successful. In obstipation it is *the* treatment, aided by enemas.

The remedies must be pushed to full effect. When one has witnessed active delirium following 1/1000 grain of atropine he learns caution. When he has pushed his strychnine dosage up to near a grain a day before getting decided evidences of its activity he learns what wide variations dosing to effect requires. Some weaken before reaching the point of effectiveness—imperfect knowledge of the drug induces timidity—the water is fearsome to him who can not swim. But when one finds that excessive doses are requisite he had better begin lower down when he renews his stock. The supply houses still partake of the human fallibility.

1358 Fulton Street.

TWO CASES OF TUMOR OF THE SPINAL CORD.*

By THOMAS A. CLAYTOR, M.D.,

WASHINGTON, D. C.

While reports of tumor of the spinal cord are much more frequently seen now than they were a few years ago they are still of sufficient rarity to justify their publication.

The following cases which have come under my observation have served to arouse my interest in a condition which, if unrecognized, is almost sure to be fatal, and yet one, which if diagnosed early enough, may many times be relieved, at least for a time, and in a few instances, completely cured.

Tumors of the spinal cord may be divided into two classes, the intra- and the extramedullary, according as they are within or without the cord substance. The more usual intramedullary growths are gummata, gliomata, sarcomata, and tuberculamata. Of these the gumma is probably the most common, while the tubercular growth is the most rare.

Tumors found outside the cord substance are again divided into the intra- and the extradural. Those most usually observed are gummata sarcomata, carcinomata, psammomata, lipomata, fibromata, and hydatids. Ostiomata and chondromata have at times also pressed upon the cord from the surrounding bony tissue.

*Read by title before the Association of American Physicians, May 14, 1912.

Case I.—G. H. R., aged forty-eight years, German, married, a printer by occupation. Was admitted to Garfield Hospital February 21, 1910.

Previous History.—Had always been healthy, one attack of gonorrhea when young, no lues.

History of Present Illness.—Four years ago began to have dull aching pain in the left shoulder, which, until July, 1909 (seven months ago), was the only symptom.

About this time the pain spread to the other shoulder and to the spine. In the fall of 1909 the pains became sharp and spasmodic; occurring when he sat in one position for any length of time or turned his body suddenly, also when at stool, or when he coughed or sneezed, and even sometimes upon swallowing. The spasms of pain gradually increased in frequency so that he was obliged to hold his head in a certain position, *i. e.* when lying down the head was inclined forward with the chin, approaching the chest. Turning the head too far to either side produced a spasm of pain which continued until the head was returned to the above described position. When standing he had more freedom of motion, but was apt to have a sharp, steady pain when the head was turned to either side rather than the spasmodic variety. It was an effort to hold the head erect, the shoulders also fell forward, especially the left. Emotion or change of temperature might bring on pain.

In October, 1909, he had entered an institution for treatment after consulting numerous physicians. Here he received electricity and various forms of baths and packs. While taking this treatment he became quite ill with fever and delirium. Strange to say, the pains subsided and did not reappear for three weeks thereafter.

In December, 1909, he was referred to an orthopedic surgeon who put him in various forms of casts which gave considerable relief, probably by limiting motion. About February 14, 1910, the legs and feet began to swell and he began to become quite weak in the lower extremities. Up to this time the symptoms had been sensory. From now on the motor disability advanced rapidly. On February 21 he had to be catheterized for the first time, though for several weeks there had been at times trouble in starting the urinary flow. About February 10 he began to notice that the rectal control was not good, *i.e.*, he was obliged to respond immediately to the desire to defecate to avoid an accident. There had been no loss of weight.

Result of Examination of the Nervous System, February 22, 1910.—Reflexes. Radial and olecranon exaggerated; abdominal absent; cremasteric weak on right, absent on left side; knee jerks exaggerated on both sides, as were the ankle jerks; toe extension more marked on the left.

Sensation.—No loss of sensation to wool anywhere. On the left anteriorly pin pricks were felt over C 8 (the eighth cervical segment of the cord) though there was hypoesthesia over this area. Loss of sensation to pin pricks from D 1 downward (the first dorsal segment of the cord). Posteriorly from D 4 downward. On the right side anteriorly, lost from D 4 and posteriorly from D 5 downward. Relative hypoesthesia to coldness over same segments. The eighth cervical area was not affected on the right side. No loss of sensation to warmth on the left side. Delayed and diminished sensation to ice over D 1 and D 2.

Vibration test.—Definite diminution in sense of vibration in D 1 as against C 7. Could feel sense of

vibration over the spinous process of the seventh cervical which could not be felt in the dorsal region. Diminution of the spacing sense in the third and fifth fingers of the left hand.

Motor symptoms.—Lower extremities quite weak, walked with difficulty. Left arm somewhat weaker than the right. Adduction of the fingers much weaker than abduction on the left, this included the thumb and little finger. Movements of all the small muscles of the left hand much weaker than normal except the abductor of the thumb and the abductor of the fifth finger. Flexion of the thumb was weak.

The more important points were as follows: The long duration of pain, the fact that it might be produced by sneezing or coughing, the attitude of spinal flexion, rigidity, with the suddenness of onset of motor symptoms seemed to indicate root pressure (tumor of the meninges). Pyramidal pressure was shown by loss of cutaneous and exaggeration of deep reflexes. Babinski's sign being more marked on the left, together with other more marked signs of left-sided involvement, suggested that the tumor was on the left side of the cord. Escape of the touch sense shows how hard it is to interrupt conductivity.

Localizing Symptoms.—Sensation: The higher level of the loss of sensation to pin pricks on the left in the absence of the Brown-Sécard syndrome, indicated that the lesion might be higher on the left side. That the lesion was as high as D 1 was indicated by complete loss of pain sense over that segment, and that it projected to C 8 was indicated by diminution of pain sense over that segment. Diminution to the sense of vibration indicated the same level, as did the hypoesthesia along the ulnar border of the left arm, and disturbance of spacing sense of the left hand.

Motility.—The same segment was indicated by the weakness of the small hand muscles and relative strength of the abductors of the thumb. The Wassermann reaction was negative. The leucocyte count ranged from 9,000 to 13,800.

Operation.—Performed by Dr. L. H. Reichelderfer, February 23, 1910. The cord was exposed by removal of the laminæ of seventh C and first D. The tumor was seen lying upon the left lateral aspect of the cord, after opening the dura, to which it was attached. It was also adherent to the pia, but could be separated from the latter without injuring it. The operation was done rapidly and skillfully, and the shock was apparently not very great. The pain was not relieved, however, nor were the nervous symptoms, except that the reflexes were no longer exaggerated. Death occurred seven days later. The temperature reached 107.2° F. shortly before death. Microscopic examination showed the tumor to be a fibrosarcoma.

Case II.—J. D., white, male, aged forty-five years. Stone-cutter by occupation. Was admitted to Garfield Hospital, January 16, 1912.

Complaint.—Pain and stiffness of the neck. His family history was negative. He stated that he had suffered from typhoid fever and malaria, and from an attack of inflammatory rheumatism which began a year before his admission and lasted more than six months. (It seems quite possible that the pain experienced in this attack was really due to the spinal tumor rather than to rheumatism.) He denied any venereal disease.

Present Illness.—Four weeks ago he began to have pain in the neck. The onset was gradual. The pain was constant and more severe when he attempted to lie down. He soon was obliged to spend his time sitting in a chair with the head forward and the chin resting on his chest. Any attempt to hold the head erect or turn it to either side caused severe pain in the cervical and uper dorsal region. The pain which at first was confined to a small area on either side of the upper dorsal region became severe in the cervical region and ran down the arms into all the fingers. About February 1 urinary incontinence developed.

Physical Examination.—A thick-set, well-nourished man, five feet seven inches in height, and weighing about 190 pounds. The head was held in the median line, well forward by anterior flexion of the upper dorsal and cervical spine, the chin resting on the chest. The neck, which was very short and thick, was buried between the elevated shoulders. The feet and ankles were swollen and edematous. The knee and ankle jerks were greatly exaggerated, ankle clonus was present on both sides; there was some doubt as to the dorsal toe flexion on the left, but it was distinct on the right. The cremasteric and abdominal reflexes were absent on both sides. The wrist jerks were bilaterally absent, the elbow jerks present. The lower right scapular reflex was feeble, hyperactive on the left. Deltoid reflex feebly present on the right side.

Motor Signs.—Gait slow and unsteady. Muscles of the lower extremities weak.

Upper Extremities.—Unable to oppose thumb and little finger of left hand. Movements slow and weak. Apposition imperfect over third finger. Flexion of left thumb weak. Apposition weaker of the right than of the left thumb. Other movements of the right side all stronger. Flexion, extension, abduction, and adduction of left wrist weaker than of the right, but feeble on both sides. Flexion of both forearms very weak. Extension stronger on the right.

Shoulders.—Abduction of both shoulders weak, as was elevation of the arms. Adduction a little stronger. Propulsion also weak. Retropulsion much weaker on the left side. Elevation very strong. Depression very weak on the left. Stronger on the right. Adduction of shoulder-blades quite strong. Contraction of the diaphragm seemed strong.

Neck—On passive motion pain was felt in the upper dorsal region of spine opposite the spines of the scapulæ, especially on the right. (A few days later the pain was felt more in the mid-cervical region.) Over the upper portion of the neck there was a decided dark red congestion of the skin, suggesting a deep-seated inflammatory condition. Percussion over the spinous processes caused pain in the lower cervical and upper dorsal regions. (Later the greatest pain was noted in the mid-cervical region.)

Sensation.—No loss of tactile sense anywhere. Some anesthesia over dorsum of right foot. Pain sense apparently lessened as far up as the umbilical region. (Later this could not be satisfactorily demonstrated.) There was no altered sensation anywhere in the upper extremities. No abnormal response to the hot and cold test anywhere, or to vibration. No abnormal condition could be demonstrated about head or neck. There was urinary incontinence.

The points worthy of consideration were the following:* The marked weakness of the flexors of

*It seems as well to leave out of account the motor findings in the hands and forearms which were rather confused.

the forearm and of the deltoids suggested that the lesion was at least as high as C 5 or C 6. The only shoulder movements retained in any considerable degree were elevation and adduction of the shoulder-blades. The former performed by the trapezius (supply derived from C 2, 3, and 4) and the elevator of the angle of the scapula (supply derived from C 3, 4, and 5). The latter is performed by the rhomboids (supply derived from C 4 and 5) and the trapezius. The apparent atrophy of the infraspinatus and supraspinatus also suggested that the lesion involved C 5 or C 6. The apparent competency of the diaphragm (C 3, 4, and 5) seemed to indicate that one or more of these segments was functionating.

Taking the above motor data—there were no sensory to guide us—it seemed probable that the lesion would be found between C 3 and C 6. The *x*-rays showed nothing abnormal in the vertebræ. The Wassermann and tuberculin tests were negative. The leucocyte count was 7,000. The lymphocytes were perhaps slightly relatively increased, being 26 per cent. to 61 per cent. of the polymorphonuclear.

Spinal Fluid.—Cell average about 1 to the cubic millimeter. Protein content much increased (strongly positive butyric-acid reaction). The temperature was somewhat irregular, ranging between 98° and 100° F., occasionally reaching 101° F. The pulse ranged from 80 to 100. The respiration from 18 to 24 to the minute. The operation, which was performed by Dr. A. A. Snyder, February 15, 1912, was extremely difficult because of the great size of the neck. The spinal cord was exposed opposite to the fifth and sixth cervical vertebræ, but apeared to be normal, and as the localization was not positive and as the anesthesia had already lasted more than two hours, it was deemed best not to go further. The patient never rallied, though he lived for five days, in great pain, except when under morphine. The temperature reached 106° F. just before death.

Autopsy—A flat tumor was found pressing upon the anterior surface of the cord opposite the third cervical vertebræ. It seemed to take its origin from the dura, and was firmly attached to the body of the vertebræ, which had the appearance of being eroded. It would appear that the cord had been exposed about an inch too low, but careful study of the specimen shows that the needle holes made in the dura for its closure during the operation began on a level with the lower border of the tumor (possibly due to shrinkage of the tissues). Had a probe been passed upward in the spinal canal the tumor must have been felt. Its removal, however, would have been practically impossible without great injury to the cord or nerve roots.

Microscopic examination showed the growth to be gumma of the dura (pachymeningitis cervicatis hypertrophica).

I may have erred in not trying an antiluetic treatment in spite of two negative Wassermann reactions (one of the spinal fluid and one of the blood), but the man's condition was so critical and he was growing worse so rapidly that I dared not wait longer before attempting operative relief, thinking that even if the suspected growth should prove to be syphilitic it might be removed and then treatment instituted.

I wish to acknowledge my indebtedness to Drs. J. B. Nichols, W. W. Wilkinson, and LaFora for laboratory work on these cases, and to Dr. T. A. Williams for his skillful aid in their clinical study.

The radicular innervation of the muscles was taken from Villger's latest classification as given by Bing in the Compendium of Regional Diagnosis, 1909.

A SIMPLE, EFFICIENT, AND ELASTIC SYSTEM FOR INDEXING CASE HISTORIES AND FILING CURRENT LITERATURE AND REFERENCES.

By E. MacD. STAUNTON, M.D.,

SCHENECTADY, N. Y.

Several years ago the writer devised a system for filing case histories so that the histories of any given class of cases would be available for immediate reference without the necessity of an elaborate system of cross indexing. A little later this same system was applied to the filing of reprints and current medical literature. The system, which is based on the principles of the Dewey library filing system, has proven so simple and efficient in our own work that I believe it worthy of reporting in detail.

One of the secrets of the success of the Dewey system in library work is the substitution of generic numerals for specific titles in the classification of books. By adapting this same principle to the classification of diseases we are at once able to eliminate the confusion arising from differences in nomenclature and, as far as necessary for filing purposes, we can eliminate the confusion arising from uncertainties or even differences in diagnosis.

The following outline shows the divisions used in our work which is limited to a general surgical practice. Those specializing in other lines of work may easily add the necessary detail to the subjects they are especially interested in. The first eleven chief divisions have to do with clinical subjects, the last three are added to show the ease with which the system may be extended to cover other subjects.

OUTLINE FOR INDEXING CASE HISTORIES AND REPRINTS.

I. *Nervous System:*
- 11.—Hysteria.
- 12.—Neurasthenia, hypochondria.
- 13.—Insanity.
- 14.—Meninges (Diseases and injuries of).
- 15.—Spinal cord (Diseases and injuries of).
- 16.—Brain (Diseases and injuries of).
- 17.—Nerves (Diseases and injuries of).
- 18.—Migraine, epilepsy.

II. *Circulatory System:*
- 21.—Heart and pericardium (All diseases).
- 22.—Thrombosis and embolism (including gangrene).
- 23.—Varicose veins, varicocele, arteriosclerosis, aneurysms.
- 24.—Blood diseases (Anemia, leukemia).
- 25.—Blood vessel surgery.

III. *Respiratory System:*
- 31.—Nose and nasal cavities.
- 32.—Antrum, frontal and ethmoidal sinuses.
- 33.—Larynx and trachea.
- 34.—Lungs (Pneumonia, bronchitis).
- 35.—Pleura (Pleurisy, empyema).

IV. *Alimentary System:*
- 41.—Hare lip and cleft palate.
- 42.—Tongue and salivary glands, esophagus.
- 43.1.—Appendicitis, acute.
- 43.2.—Appendicitis, chronic.

44.1.—Stomach—Surgical diseases.
44.2.—Stomach—Medical diseases.
45.—Liver and gall bladder.
46.—Pancreas.
47.—Small and large intestines.
48.—Rectum and anal region (Fissure and fistula in ano—hemorrhoids).
49.—Enteroptosis.

V. *Genitourinary System and Gynecological:*
51.—Kidneys and ureters.
52.—Bladder.
53.—Prostate.
54.—Urethra and penis.
55.—Testicles, epididymis, vas, and seminal vesicles.
56.—Uterus and endometrium, obstetrics.
57.—Malpositions of the uterus.
58.—Cervix and perineum, vagina.
59.—Tubes and ovaries.

VI. *Hematopoietic System and Unclassified Glands:*
61.—Lymph nodes; spleen—nontuberculous diseases.
62.—Lymph nodes—tuberculous.
63.—Thyroid (Goiter).
64.—Tonsils and adenoids.
65.—Skene's glands, Bartholin's glands.
66.—Mammary glands.
67.—Adrenals, pituitary, thymus.

VII. *Osseous and Muscular System:*
71.—Bones—nontuberculous affections.
72.—Bones—tuberculous.
73.—Joint affections—nontuberculous, also bursitis—synovitis.
74.—Joint affections—tuberculous.
75.—Flat foot.
76.—Spinal curvature, ligament strains, contractures.
77.—Myalgia.
78.—Club foot—congenital malformations.

VIII. *Special Senses. Skin and Derivatives:*
81.—Eye.
82.—Ear.
83.—Mastoid.
84.—Skin, hair, nails, and teeth.

IX. *Tumors:*
91.—Benign tumors (except myoma), cysts.
92.—Myoma uteri.
93.—Carcinoma, hypernephroma.
94.—Sarcoma.

X. *Infections:*
101.—Septic infections. Infections of extremities—abscesses.
102.—Peritonitis, adhesions. (See also under special organs.)
103.—Gonorrhea.
104.—Syphilis—chancroid.
105.—Infectious diseases—influenza, typhoid, etc.
106.—Tuberculosis. (See also under special organs.)

XI. *Traumatisms:*
111.—Fractures.
112.—Lacerations, stab and gunshot wounds, foreign bodies.
113.—Sprains, dislocations.
114.—Contusions.
115.—Hernia.
116.—Burns.
117.—Shock and hemorrhage.
118.—Electric shock.

XII. *Therapeutics and Pathology:*
121.—Medicines and drugs.
122.—Poisons.
123.—Diet lists.
124.—Anesthesia.
125.—General pathology.
126.—Pathological technique, laboratory methods, etc.
127.—Theoretical immunity, anaphylaxis, etc.
128.—Opsonins and vaccines.
129.—Antiserums, hemolysins, and allied sera.

XIII. *Technique, Hospital Problems, Nurses:*
131.—Surgical technique—operating room.
132.—Surgical technique—preparation of patient and after treatment.
133.—Surgical technique—suture materials, instruments, etc.
134.—Hospital construction, furnishings.
135.—Hospital management.
136.—Nursing.
137.—Nurses' lectures and addresses.
138.—Medical society.
139.—Medical education.

XIV. *Catalogues, Etc.:*
141.—Drug lists.
142.—Catalogues—laboratory supplies.
143.—Catalogues—operating room fixtures.
144.—Catalogues—instruments.
145.—Catalogues—orthopedic apparatus.
146.—Catalogues—hospital beds and fixtures.
147.—Hospital reports.

The system is applied to the cross indexing of case histories as follows: Mrs. B., seen in consultation, presents an old perineal tear with cystocele, fairly marked bladder symptoms, an umbilical hernia and a reasonably clear history of gallstones. When her history is filed it is given the numbers 58 (perineum), 52 (bladder), 115 (hernia), 45 (gall bladder). If the physician himself has not time to add the numbers any interne, or assistant, or an experienced history clerk can add the numbers with all the accuracy that is really necessary.

No further cross indexing is necessary, for whenever it is desired to review the histories of any given class all that is necessary is to go through the alphabetically filed histories and take out those with a number corresponding to the subject under investigation. It is then an easy matter to select the cases desired for study and if necessary have these transferred to an appropriately systematized card.

The original case histories are kept in suitable sized envelopes and filed alphabetically under the patient's name. In this way all data concerning a given patient, such as special laboratory reports, correspondence, etc., reaches a final resting place in the same envelope.

In applying the same system to the filing of reprints it is only necessary to have a series of linen bound pasteboard boxes such as will fit like books on a shelf, assigning to each box a number corresponding to each separate subject. I use cloth covered pasteboard boxes, ten inches long, one and one-half inches wide, and ten inches deep. Such boxes can be obtained from any paper box company for about ten cents apiece. Each piece of literature relating to diseases of the gall bladder is given the number 45 and filed in box 45; likewise goiter literature is filed in box 63, and kidney literature in box 51.

If as a result of special work along any one line the papers on this subject become too numerous to file in one box it is only necessary to add additional boxes with the same number, or the subject may

be further subdivided to suit the individual requirements of the user. Take for instance the kidney (No. 51). My literature on this subject is filed as follows:

51.1.—Acute and chronic nephritis.
51.2.—General articles on kidney surgery.
51.3.—Renal and ureteral calculi.
51.4.—Hydronephrosis—pyogenic infections.
51.5.—Tuberculosis.
51.6.—Movable kidney—traumatisms.
51.7.—Renal tumors—cystic kidney.
51.8.—Diseases and surgery of the ureter.
51.9.—X-ray—cystoscopy—functional tests.

When the clinical histories are carefully studied in the course of some special investigations it may be advisable to classify them into sub groups, which can be done by adding decimals the same as in the case of the reprints and references, but as a general rule I have found it advisable not to attempt too rigid a classification of the histories, and certainly this should never be done except as a result of an especially careful study of the cases.

At first the boxes were used only for reprints and references to important articles, but it was found so much easier to refer to papers filed in this way than to hunt them up in bound periodicals that for some time past all important papers appearing in the current journals have been cut out, the pages fastened together with a Hotchkiss stapler, and the article filed the same as a reprint. Occasionally two important articles will overlap on a page in the same journal, which necessitates noting that the missing page will be found attached to an article filed in another box.

Since instituting the above filing system our histories have always been ready for immediate use, and I have been able to keep several assistants occupied a good share of the time analyzing the material from various viewpoints and comparing our experiences and results with those reported by other workers in similar fields. I believe that this is the only way in which one can keep a true perspective of the knowledge gained by his own experience and yet most men, even those who keep accurate histories, neglect this chiefly because their histories are not so filed as to be easily available for reference.

The advantages of a simple, workable system for filing current literature are so obvious as to need no further comment.

613 State Street.

True and False Intestinal Flatulence.—D. Roberts concludes that gas varying in amount with the diet is normally generated in the human intestine. Normally it is absorbed, or if convenient, passed when it gives rise to a feeling of slight pressure. The hypochondriac may be apprehensive over just this normal condition. Abnormal flatulence depends on an excessive fermentation or the abnormal accumulation of a normal flatus or a combination of the two conditions. Too much reliance is placed on antifermentative drugs and digestive ferments to relieve the complaint of flatulence. Too little attention is given to benefits to be derived from proper regulation of the bowels through whatever measures may be necessary for the particular case. Attacks of abdominal tympany should be regarded with suspicion and search made for mechanical obstruction or local peritonitis. In a large majority of instances the complaint of gas in the bowels means merely that there is an abdominal discomfort and without sufficient reason it is attributed to gas. Too much stress cannot be laid on the importance of recognizing cases of false flatulence due to anatomical lesions in the abdomen or to disturbances of intestinal peristalsis.—*Long Island Medical Journal.*

Medicolegal Notes.

Basis of Opinion Evidence.—In an action for injuries a physician testified to an examination he made of the plaintiff approximately a month after the accident, and to his finding at that time a bruised place on her hip about three inches square, and that her right ovary was very sensitive and tender, and her womb considerably enlarged and inflamed. He further testified that such a bruise in that region would, as a natural result, produce the condition he found in the womb and ovaries. It was held that such opinion was admissible, being based on objective conditions, and not entirely on subjective conditions. The fact that he was originally called to treat the plaintiff for the purpose of testifying as a witness in her behalf did not render his evidence inadmissibility. Any contention against the evidence could only relate to the credibility of the witness.—St. Louis Southwestern Ry. Co. v. Borne, Texas Supreme Court, 145 S. W. 1186.

Practising Without Authority—Evidence.—An information charged that the defendant, without having been granted a certificate to practise medicine in the State of Montana, "did prescribe and direct for the use of one Emma Van Orsdel, a person then and there afflicted with a certain physical ailment of the body, to wit, sickness resulting from pregnancy, a certain appliance or apparatus, to wit, a certain surgical instrument, commonly known as and called forceps." The Montana Rev. Code, § 1591, 8544, is directed against the offense of practising medicine or surgery without having first obtained a certificate from the State Board of Medical Examiners. The information, however, having charged that the accused's offense consisted in the giving of a particular prescription, the conviction could only be sustained by proof of that particular act. This being awaiting, the judgment of conviction was reversed.—State v. Morris, Montana Supreme Court, 122 Pac. 917.

Regulation of Practice—Discretionary Power of State Board of Examiners.—In an action for a writ of mandate against the State Board of Medical Examiners of the State of Idaho, the question presented was: Can the medical board require an applicant to pass an examination where he holds a license from a medical board of another State where the board of such other State required an examination on all the subjects required by the board of the State of Idaho, and the applicant was awarded an average grade of not less than 80 per cent. and has in all respects complied with the requirements of the statute. The question was answered in the affirmative, the Idaho statute regulating the practice of medicine and surgery within the State being held to confer a discretionary power upon the board. Under the provision of Section 1342 of the Idaho Revised Codes the Legislature grants power to the board of examiners to determine the qualification of applicants to practise medicine: First, by examination; second, without examination upon the applicant presenting to the board satisfactory proof of the existence of certain facts with reference to the applicant's qualification. When application is made for license without examination certain questions of fact are to be determined: First, that the applicant has been licensed to practise medicine by a similar board of another State; that is, whether the applicant has been licensed, and whether it was by a board similar to the examining board of the State of Idaho. Second, that the applicant holds a certificate of registration showing that an examination has been made by the proper board of any State in which an average grade of not less than 80 per cent. was awarded to the holder thereof. Third, that the applicant was the legal possessor of a diploma from a medical college in good standing in any such State, which said diploma may be accepted in lieu of an examination as evidence of qualification. Fourth, that the scope of the examination was not less than prescribed in the State of Idaho.

In determining these questions of fact it was held that the board is not required to accept the statement of the applicant or his affidavit as conclusive proof that the board of any other State was in fact a similar board to the board of examiners of the State of Idaho, or that the applicant holds a certificate of registration of the kind required by the statute or as to any other of the matters required by the statute to be established. The statute does not limit the board in determining the qualification of an applicant to any particular kind of proof, and the board are possessed of power to determine these questions upon such evidence as will satisfy their minds as to whether or not the applicant is qualified as required by the law and the rules of the board. The court will not interfere with the discretionary power conferred upon the State board. The write was denied.—Barton v. Schmershall, Idaho Supreme Court, 122 Pac. 385.

New York, November 2, 1912.

THE BIOLOGICAL ASPECTS OF PRIMOGENITURE.

FROM the dawn of history the firstborn have enjoyed a peculiar distinction, and in many ways have been granted certain privileges over other children in the same family. Popular tradition and biblical history furnish many illustrations of the prestige of the eldest member of the family. The laws of succession in monarchies have been based upon the recognition of the supposed superiority of the firstborn son. The instinctive bond so closely knitting the parents to their first child finds its social expression in the priority which the latter enjoys in social and ceremonial functions. The laws of primogeniture which establish the right of the firstborn to take by descent the real property of a deceased ancestor were based upon the feudal customs of medieval times, though ancient Hebrew and Hindu traditions also recognized this right. This mode of inheritance has been generally abandoned, but it still survives as an outworn relic in conservative England. The injustice which in many instances has deprived the younger children of a deserved patrimony has furnished a valid basis for the abolition of these laws. Nevertheless even in countries in which the latter are not operative one may readily recall instances in which the bulk of large estates is left to the eldest male heir, presumably for the purpose of keeping these estates intact. The precious heirlooms in many families are still carried from generation to generation through the eldest in the line.

Is there any biological basis for the laws of primogeniture apart from the instinctive regard for the firstborn? Does the oldest child possess any advantage over the other children in its bodily and mental vigor? Overwhelming evidence enables one to answer these questions in the negative; indeed recent investigations have shown that the firstborn labors under certain disadvantages so far as the susceptibility to disease is concerned. The study of this subject leads to the larger one of the relation between the numerical position of an individual in a family and his susceptibility to disease.

The mathematical methods of the biometricians, led by Karl Pearson, have shown that among tuberculous patients the firstborn provide a larger number of subjects than any of the other children. This observation was first made by W. C. Rivers in looking over the records of the Crossley Sanatorium, England. Exact statistical methods applied to these cases by Pearson, as well as to larger series reported by Brehmer and Riffel in Germany, confirmed this observation. It is interesting to note that Brehmer provided part of the material which was destined to overthrow his own teaching that the latest born are the most susceptible to tuberculosis.

But this is not the only disease in which a preference is shown for the firstborn. Insanity and criminality show a preponderating incidence among the eldest children. Pearson has pointed out that "in certain cases at least of constitutional defects which are inherited, the earlier members of the family are more likely to suffer than the later." This fact may account for the degenerative manifestations in those social groups, such as the peerage, which are recruited largely from eldest sons. The decadence of not a few of the reigning houses of Europe may be attributed to the same cause. Recent events may be recalled in which the escapades of crown princes have played a conspicuous part.

The special morbidity of the firstborn may be due to other causes than an inherited susceptibility. A tendency to coddle, to pamper, and to indulge the first child may account for a part of its vulnerability to disease. An apparent contradiction to this phenomenon is afforded by the fact that the older members of a family live on an average four to five years longer than the younger ones. Among the lower classes inexperience in the care of the young may account for the greater morbidity of the first children. Another factor that must be borne in mind is the importance of the influence of immaturity in the parents in the production of handicapped children. In the first children that are born this influence is most apt to be operative.

On the other hand, it must be recognized that the reverse order of morbidity may occur. *A priori* it may be reasoned that with the rapid increase in the size of families among the poorer classes, the resulting overcrowding of the home and limitation of the means of subsistence work disastrously to the later born. Frequent gestation and parturition sap the strength of the mother and result in the birth of weaker and less resistant offspring. In the large families of the tenement population the chances of zymotic infection among the younger children are increased by the fact that the older children bring contagion into the home from the school and playground. It may be concluded that, other things being equal, as the size of the family becomes an inordinate one, particularly if the surrounding conditions are not of the best, the chances of disease increase with each new arrival in the family. It has been noted that frequent childbearing, particularly among the poor, is apt to favor the development of rachitis in the later children.

The above facts indicate that the subject of the pathological aspects of the order of birth is not an academic one. In these days when the problems of eugenics, limitation of offspring, maternity rewards, and maternity insurance are being so freely discussed, it is a matter of practical importance that definite information should be available on the numerical phases of family growth. Careful study

by Powys of Australian vital statistics has shown that a family of five or six children is correlated with a greater longevity in the parents than one in which the number of children is greater or less than this figure. Recognizing the reciprocal disadvantages of inordinately large families, disadvantages that are both fiscal and physiological, one may at least extenuate a certain degree of what has been aptly termed "reluctant parentage."

A plea should be made for the definite recording in all anamneses of the individual's ordinal position among the children of a family. It is unfortunate that this phase of history-taking has been almost wholly neglected. The life insurance companies have at their disposal a mass of figures pertaining to the order of birth and its relation to morbidity that cannot fail when properly collated and studied to be of value in throwing light upon this subject.

POLIOMYELITIS.

Perhaps the most important happening at the recent Congress on Hygiene and Demography, held in Washington, was the discussion on and announcements with regard to poliomyelitis by some of the best kown authorities on the subject of the world. In Sweden for some time past the State Medical Institute of Sweden in the persons of Professors Alfred Pettersson, Arnold Josefson, Carl Kling, and Wilhelm Wernstedt has been prosecuting careful and thorough investigations into all phases of the malady. A report of these investigations was given at the Congress, and Prof. Pettersson at the symposium on poliomyelitis dealt with its modes of infection and its prevention, its symptomatology and pathology in monkeys, and with the epidemic of poliomyelitis in Sweden in 1911-1912. It should be borne in mind that the Swedish investigators have had peculiarly favorable opportunities for studying the disease. The outbreak of poliomyelitis, which began in Sweden last year and which continued during the present year with increased severity, has exceeded already in wideness of scope and severity any other known epidemic. In the year 1911, 3,840 cases were recognized and from January to the middle of August of the present year no fewer than 1,458 additional cases have been reported.

The results of these investigations strongly uphold the theory of direct transmission of poliomyelitis from one person to another. Not only is the patient himself in the acute stage a potent source of infection but he remains so during the convalescent stage. Furthermore, for the first time, the existence of carriers has been established experimentally, and likewise that carriers and abortive cases are more numerous by far than the typically paralytic cases. The discovery of the existence of carriers is most important and from the fact that carriers receive the virus upon their nasopharyngeal mucous membranes from the external surroundings probably by means of infective secretions, it may be fairly presumed that affected persons have received the virus in a similar manner. Moreover, it would seem as if Pettersson's discovery confirmed the theory of Flexner that the disease is communicable from person to person through the upper respiratory passages or that the microorganisms may be conveyed by dust and wind.

Dr. M. J. Rosenau's announcement that he had found the stable fly responsible for the spread of poliomyelitis appears to clash with the findings of Pettersson. However, while attaching most importance to direct transmission and to the nasopharynx as the seat of entrance of the virus, Swedish expert opinion admits the possibility of indirect transmission by insects and inanimate objects. True it is that inoculation experiments with saline infusion of flies, caught by poliomyelitis patients in the epidemic wards, were negative, as also were those with fleas taken from houses in which dwelt patients acutely ill with poliomyelitis or collected after parasitic existence on an infected monkey, yet further demonstrations may show that the results of Rosenau's experiments were correct. It is instructive to note that Josefson produced experimental poliomyelitis with saline extracts of a handkerchief and embroidery work which had been used by patients acutely ill, even after the material had been allowed to dry for some days before making the extract. These facts, too, bear out previous observations by Neustaedter and other investigators that the virus could be found in dust and remain active for 31 days in sterile milk, its activity probably accounting to some extent for the frequency of the disease in infants who, crawling on the floor, would have the most favorable facilities for getting the infected dust on the nasopharynx. In short, the Swedish investigators conclude that fleas and other blood-sucking insects may be of importance in house epidemics, but play no great part in the production of extensive epidemics which are mainly due to direct transmission. As for the frequency of the virus in the intestine, it is largely owing to the swallowing of the infected nasopharyngeal secretion. Flexner again supports this view by proving the capacity of the virus to withstand the antiseptic action of the gastric juice.

Undoubtedly a very strong case for direct transmission has been made out and it follows that isolation will be generally accepted by the medical profession as the rational method of controlling the spread of poliomyelitis and in time of stamping it out. Enough is now known to insist that the disease everywhere be made notifiable.

FAILURE OF THE VOICE.

Persons who use the voice overmuch, as singers, public speakers, ministers, and lawyers, frequently suffer from a failure in its production. Clergyman's sore throat has become almost a synonym for one form of voice failure, and all great singers are compelled to use the most extraordinary precautions in order to retain the use of that gift or accident of nature by which they are enabled to reap a golden harvest.

Cyril Horsford in the *Practitioner* for October, 1912, suggests reasons why the voice fails. The failure of the voice must be dependent on either (1) faults in the method of use; (2) faults in the phys-

ical condition of the vocal instrument. The principal vocal fault encountered is throatiness, and Horsford refers to two important influences which bring about the condition—rigidity and force. Rigidity is one of the commonest of all bad influences and is the opposite to elasticity, which is essential for perfect vibration and muscular efficiency. It is not until all rigidities are removed that the vibrations can reach the ends of the resonating cavities such as the base of the skull above, the bridge of the nose, the lips, and the teeth in front. If the vibrations do not reach these parts, tone is obtained, partly, at any rate, by force, which means putting more pressure on the vocal cords than they have been trained to withstand. Although force is usually associated with vocal faults, it is not invariably so. As Horsford points out, it may be merely strain on the vocal cords when they are unfit temporarily, weak muscularly, or young and unresistant. In this connection a warning is given with regard to using the voice too much when young, for ambitious young singers should bear in mind that before displaying their vocal instrument, it is necessary to build it, for in the untrained voice the structural elements are, when used, jumbled together in an inartistic manner, and will eventually injure each other.

As for faults in the physical condition of the voice, the author insists upon the fact that the vocal instrument does not consist merely of the larynx or box, in which are situated the vocal cords, but of the whole body from the crown of the head to the soles of the feet. The cultivation of the brain or organ of the mind is an essential part of voice training, for artistic if not actual vocal failure is frequently attributed to deficiency in this department alone. Physical fitness of the body as a whole is essential for the preservation and perfect development of the voice, and anything which improves the bodily health will, as a rule, benefit materially the voice.

Finally, Horsford concludes that with all due respect to voice training as an art, and to the great skill frequently displayed by many gifted masters, the safe and effective training of the singer will be more certainly obtained by the cooperation of the singing master and laryngologist. Undoubtedly, many voices are injured and some spoiled by one not knowing how to use them. The remark applies to the public speaker as well as to the singer. It would be well, then, if budding Websters and embryo Pattis or Carusos took the advice of the writer in the *Practitioner* and instead of abusing their vocal organs, exercised discretion in their use and allowed themselves to be guided to the proper mode of singing and speaking by those possessing the requisite artistic and medical knowledge.

MEDICAL ASPECTS OF THE WAR IN THE EAST.

The problem of the care of the injured is one that surpasses in difficulty any other that arises in modern warfare. When the movement of armies and their engagement in battle have acquired the momentum so characteristic of the present hostilities in the Balkans, these difficulties are greatly magnified. The narrow theater of warfare so near to the capitals of the respective combatants may facilitate the less urgent treatment of the injured men, but this depends upon the presence of adequate hospital accommodations in these cities, and upon a good system of transportation. Although the allies have carefully planned their lightning-like campaign, they have failed to provide sufficient medical officers and suitable ambulance equipment to care for the large number of wounded that have fallen in the first days of the war. At Belgrade and at Athens there are large and up-to-date military and civil hospitals that are sufficiently equipped to deal with the major surgery of war. Bulgaria and Montenegro are not so well provided for. The Red Cross of the allies and the Red Crescent of the Turks, whose insignia is the red half-moon, are experiencing more than in any other recent war the intense strain upon their resources. The British Red Cross has already tendered its services and the cessation of the war in Tripoli has released a number of valuable ambulance units. According to the *Hospital* of London, "the erection of large emergency hospitals on the pavilion plan appears to be the best way out of the difficulty so far as accommodation is concerned, but the provision of suitable medical men and nurses will not be so easy."

The civilized world again stands aghast at the horrors of war. Hardly have the echoes subsided from the congress at which representatives from almost every nation met to discuss the conservation of human life than there begins anew the devastation of shell and shrapnel, the awful slaughter of saber and bayonet. Universal peace is still the idle dream of philanthropists and the professed goal of smiling statesmen. The war in the Balkans, which has so long hovered like a threatening cloud over the peace of Europe, has now descended like a thunderbolt. If it were a final struggle between Christendom and Islam, between civilization and barbarism, one might find some justification for this strife. But the secret designs of diplomacy hide behind the crescent and the star. In the meantime, weary eyes will keep a vigil over the groaning victims of the battlefield and skilled hands will bind the wounds and relieve the agony of those swept into the pitiless combat.

The "Penny Signs" in Pleurisy and Ascites.

Several years ago Professor Pitres of Bordeaux drew attention to a new sign in pleurisy with effusion, based upon the transmission of the sound obtained by tapping one coin on another which he termed the "signe du sou." In the *Medical Press and Circular,* October 9, 1912, it is stated that Pitres' sign may be of the greatest assistance in the diagnosis of pleural effusion, often a question of some delicacy. Janney, in a recent thesis, says the sign is also of value in ascites. In order to elicit Pitres' sign in a case of pleurisy, a coin is placed flat on the chest, in front, just below the nipple, and an assistant taps it with another coin, striking vertically. While this is being done the observer listens over the back and side of the thorax. If the interior of the thoracic cavity is occupied by a homogeneous medium, either solid or liquid, which

conducts sound more perfectly than normal pulmonary tissue, the percussion sound is audible as a clear ringing silvery vibration. Consequently the "penny sign" is not pathognomonic of pleural effusion, but as massive indurations of the pulmonary parenchyma are much more uncommon than pleural effusion, this sign, taken in conjunction with the more or less complete series of other signs and symptoms, will in most cases indicate the presence of a liquid effusion into the pleural cavity. As the laws of the transmission of sound are the same in the abdomen as in the thorax, Lesieur and Rebatta have extended its use to the diagnosis of the existence of ascitic fluid in the peritoneum. In a normal abdomen we never get a silvery clear sound. Although then the "penny sign" is not pathognomonic of ascites any more than it is of pleural effusion, yet it shows the presence in the abdomen of a homogeneous medium either liquid or solid in an uninterrupted layer. Therefore, when the sign is positive we still have to differentiate ascites from a fibroid tumor or pregnancy, and as a rule this can be done by noting that in the first case, in order to obtain the silvery tone we have to percuss in the lower parts of the abdomen, whereas in the case of a fibroid tumor or pregnancy the sign is perceived when percussing over the epigastrium.

The Toxicity of Potassic Chlorate.

When potassic chlorate gargles and troches first came into general use by the public fears were freely expressed that enough of the salts could be absorbed to cause poisoning. Patients were cautioned against swallowing the solutions and pellets. In bloody urine without apparent cause the informed physician used to direct inquiries to the possibility of chlorate of potassium ingestion in toxic amounts. But this overcaution, for such it seems to have been, died away to a large extent. The remedy had once been used internally in desperate maladies, both acute and chronic; and the frequent cases of poisoning must be attributed in part to the diminished powers of resistance of the gastroenteric mucosa and kidneys and of the erythrocytes. A study of the literature fails to show any considerable number of cases in which moderate doses have caused toxic symptoms in relatively sound subjects. Quite recently, however, the opinion has been expressed by one of the world's greatest toxicologists among others that the too free use of dentifrices which contain a large proportion of potassium chlorate is a menace to the community. So widespread has this belief become that Bachem, in a paper contributed to the *Muenchener medizinische Wochenschrift* for October 1, attempts to decide the question once and for all. He finds that in former years the drug was given in presumably therapeutic doses which equaled forty grams in 24 hours, and that even with such prodigious quantities toxic phenomena were not anticipated. A legend grew up, however, that the young child was not to be given this remedy, and it occurred to the writer to test it upon young puppies for a quick determination of its general toxic properties. The animals received 30 grams daily for six weeks and the excreta were controlled. The drug was readily eliminated, and there was no retention nor cumulation. The main prop of the poison dentifrice theory, that poisoning could result from continuous daily use through slow cumulation, was thus shattered. Moreover the animals showed normal growth rate. Eventually the animals were killed and no trace of renal lesions was found. The gastric mucosa showed no evidence of irritation (the drug had been administered well diluted in milk). Spectroscopic tests showed not the slightest evidence of methemoglobinemia. According to toxicologists dogs are more sensitive to the action of potassic chlorate than are other laboratory animals; hence they were chosen for this experiment instead of rabbits and guinea pigs.

The Results of the Pasteur Treatment of Rabies.

A year ago we called attention to the excellent record attained by the Pasteur Institute of Paris with their antirabic inoculations. Dr. Viala's report for 1911 (Annales de l'Institut Pasteur, vol. xxvi, p. 653) shows that this high standard has been maintained. During the year there have been treated 342 persons with no deaths. Of this number 76 were bitten by animals in whom the disease was proven by inoculation, 114 by animals declared rabid on veterinary examination, and the remaining 152 by animals suspected of rabies. Since its foundation in 1886 the institute has administered the treatment to 33,388 persons, of whom 128 (0.38 per cent.) have died; there have been no deaths during the past two years. These results are in the highest degree impressive and indicate the excellent quality of the work that is being done in the lines of preventive medicine. Perusal of the full report is recommended to those who can see no good in animal experimentation.

News of the Week.

Civil Service Examination.—The United States Civil Service Commission announces a competitive examination for men only, to be held on November 20, 1912, for the purpose of filling a vacancy in the position of mine surgeon in the Bureau of Mines, at a salary ranging from $2,000 to $3,000 per annum. The person appointed to this position will be expected to give instruction to the first-aid miners of the Bureau, and to supervise their work, and to observe and report on sanitary conditons in and about the mines, and be prepared and able to enter the mines with rescue forces immediately after accidents, etc. Applicants must be citizens of the United States, under forty years of age, and graduates of a reputable medical college, and must have had not less than three years' experience in medical and surgical practice about coal mines. Special credit will be given for experience in rendering first aid to the injured, etc. Persons meeting the requirements will be allowed to enter the examination on application to the United States Civil Service Commission, Washington, D. C.

Navy Medical Reserve Corps.—The organization of the medical reserve corps which was authorized in the Naval Appropriation Act of August 22, 1912, is now proceeding under the direction of Surgeon-General Stokes of the Navy, who is interesting physicians throughout the country in the naval service. Prior to the organization of this corps the Navy Department could not take advantage of the cooperation of surgeons outside the service, but will now have the benefit of their advice in many practical problems. The members of the corps will not be called upon for active duty except in time of war.

Child Hygiene.—The work of child hygiene in New York City has been further helped by the appointment by Mayor Gaynor of Dr. Ira S. Wile as a member of the Board of Education, the Mayor stating that his object in making the appointment is to have Dr. Wile enter systematically into the work of examining the health of all the children in the public schools and to take scientific means of prevention and cure. The Mayor also suggested the creation of a standing committee of the Board for carrying out these designs. At a subsequent meeting the Board showed its approval of the Mayor's plans for the improvement of physical conditions among the school children and provided for the appointment of two additional physicians for the examination of mentally deficient children, of an assistant inspector of ungraded classes, and for a social worker to visit the parents of children of this sort.

Fordham Clinic.—A certificate of incorporation was granted recently to the Fordham University Consultation Clinic, New York, which has for its object the erection, establishment, maintenance, and conduct of a dispensary to provide facilities for the instruction of physicians and students of medicine and pharmacy at the Fordham University School of Medicine. The directors are Dr. James J. Walsh, Dr. Thomas J. McClusky, and Dr. Joseph J. Keating.

Gift to Johns Hopkins Hospital.—The Board of Trustees of the Johns Hopkins Hospital, Baltimore, recently received from Mr. J. B. Brady of New York, a gift of $200,000 to be used in founding the James Buchanan Brady Urological Institute as a separate unit of the hospital. In addition, Mr. Brady will, during his life, pay to the trustees the sum of $15,000 yearly for the maintenance of the institute, and will make ample provision for its continued support in his will. This will be the first institute of its sort in this country, although London and Paris already have such hospitals and Berlin is about to construct one. The Johns Hopkins Hospital plans to erect a six-story building with special laboratories for research, and accommodations for both public and private patients. The gift is made because of Mr. Brady's interest in the hospital following his recent stay there as a patient.

Dr. Wiley's Successor.—It is reported that President Taft has decided upon the appointment of Dr. Carl L. Alsberg as successor to Dr. Wiley, though no formal announcement has been made. Dr. Alsberg at present occupies the position of chemical biologist in the Bureau of Plant Industry of the Department of Agriculture at Washington. He is a graduate of Columbia College in 1896 and of the College of Physicians and Surgeons, New York, in 1900, and was formerly instructor in biological chemistry in the Harvard Medical School. He has also taken courses in chemistry and biological chemistry in some of the German universities. He is only thirty-five years old.

New Research Institute.—Reports have come from France of the establishment in Paris by a wealthy foreigner of a medical research institute similar in some respects to the Rockefeller Institute, New York. It is said that for the purposes of the institute a large hotel building has been purchased and that the installation of the necessary equipment can be accomplished in three months. No announcement has been made as to the scientific staff of the institute.

Smallpox in a School.—A small epidemic of smallpox has broken out among the students of the South Lancaster Academy, Clinton, Mass., and forty cases and one death have occurred. The Massachusetts State Board of Health is investigating the situation.

Village Typhoid Swept.—The epidemic of typhoid fever which started in Troy, Pa., recently, has continued to develop, and on October 26 172 cases were reported in a village of 1,500 inhabitants. The infection has also spread to several nearby towns.

Pittsburgh Smallpox Free.—The Health Department of Pittsburgh, Pa., reports that the city is now free from smallpox. The appearance of several cases of the disease some time ago caused some anxiety.

Disease Among Eskimos.—For the first time on record infantile paralysis has appeared among the Eskimos of Alaska. Reports have been made to Surgeon-General Blue of the Public Health Service in charge of the health of the Eskimos, of five cases of the disease and one death at St. Michael's and of ten cases and two deaths at Unkaleet, forty-five miles distant. Three cases have also been reported in Sitka.

Railroad Men's Hospital.—The Missouri-Pacific Railroad has made a transfer of its hospital funds and property to its employees, who have for many years contributed small sums out of their salaries toward the support of the hospital service. The railroad company turned over to a Board of Hospital Managers, elected by the employees, the sum of $193,767, and in addition the large hospital building in St. Louis with its equipment and furnishings, and the surrounding grounds, the total value being about $250,000. The railroad started its hospital service about thirty years ago and has handled the property and money received from its employees until recently, when it was determined that the control of the funds should be turned over to the men themselves.

Protest Against a Tuberculosis Hospital.—The City of New York has protested to the State Health Commissioner, Dr. Eugene H. Porter, against the proposed erection by Westchester County of a tuberculosis hospital at Croton Lake in the northern part of the county. The Water Supply Department of New York contends that the hospital at Croton Lake will be a menace to the water supply of Manhattan, because two streams which flow through the Griffen farm, which is the proposed site, empty into Croton Lake, not far from the intake of the new Catskill Aqueduct.

Centenarians Indeed.—Joe Manitou, an Indian chief of the Pottawattomie tribe, died on October 24, at his home in Traverse City, Mich., at the reputed age of 120 years. Until recently his memory, it is said, was clear and he could recall the details of the early Indian wars in which he had participated.

Mr. Macagor Wise of Beaver Brook, N. Y., celebrated his 109th year recently by paying a visit to New York City, where he noted many changes since his first recollections of it.

Clinical Lectures.—Dr. Frederic Bierhoff announces a series of clinical lectures and demonstrations upon genitourinary and venereal diseases, with particular reference to the more modern methods of diagnosis and treatment, at the West Side German Dispensary, 328 West 42d street, New York, on Monday evenings at 8:30, beginning on November 4. The course will cover a period of about

three months, and will be free to the medical profession and to advanced students in medicine.

Harvey Lecture.—The third of the present series of Harvey Lectures will be delivered by Prof. Joseph Erlanger of the Washington University Medical Department, St. Louis, at the New York Academy of Medicine on the evening of November 9, at 8:30. Prof. Erlanger's subject will be: "The Localization of Impulse Initiation and Conduction in the Heart." As heretofore the lectures are open to the public.

Boys Cleaner Than Girls?—The annual report on vacation playgrounds in New York City shows that during the year ending September, 1912, the free baths in the public schools throughout the city were well patronized. The attendance reached 603,328 boys and 213,325 girls, from which figures and from the fact that the girl bathers, as a rule, confined their ablutions to the afternoon hours, while the boys bathed at all times, the newspapers conclude that the boys of the city go in more for personal cleanliness than do the girls, which is somewhat doubtful logic.

Gifts to Charities.—The Eastern Maine General Hospital of Bangor, Me., receives a bequest of $4,000 by the will of the late Mrs. G. B. Perry of Middletown, R. I.

By the will of the late Mrs. Emily S. Hutchinson of Greenwich, Conn., the Helping Hand Association of Peekskill, N. Y., receives a bequest of $10,000 for the Peekskill Hospital.

The Summit Free Hospital and the Fresh Air and Convalescents' Home of Summit N. J., receive bequests of $1,000 and $500, respectively, by the will of the late Mr. William Z. Larned.

By the will of the late Sarah A. Anderson of Philadelphia, the sum of $500 is bequeathed to the Episcopal Hospital of that city.

By the will of the late Harriet C. L. Hopkins of Philadelphia, who died recently at Otsego, N. Y., an estate of $7,000 is to be equally divided between the Philadelphia Home for Incurables and the Protestant Episcopal Home for Consumptives.

Dr. H. T. Summersgill, superintendent of the New York Post-Graduate Medical School, has been offered by Mayor Hunt of Cincinnati the position of superintendent of the Cincinnati City Hospital.

Dr. William Seaman Bainbridge of this city has been appointed Consulting Gynecologist to the Ossining Hospital, Ossining, N. Y.

Mississippi Valley Medical Association.—At the annual meeting of this association, held in Chicago, October 22-24, the following officers were elected: *President,* A. E. Sterne, Indianapolis; *First Vice-President,* D'Orsay Hecht, Chicago; *Second Vice-President,* Hugh Cabot, Boston; *Secretary,* H. E. Tuley, Louisville; *Treasurer,* S. C. Stanton, Chicago. The next meeting will be held in New Orleans the last week in October, 1913.

East Tennessee Medical Association.—At the annual meeting held in Johnson City on October 10 and 11, the following officers were elected for the ensuing year: *President,* Dr. Henry M. Cass, Morristown; *Vice-Presidents,* Dr. James P. Randall, Johnson City, and Dr. James G. Eblen, Lenoir City; *Secretary-Treasurer,* Dr. H. P. Larimore, Chattanooga.

Railway Surgeons.—At the annual session of the Surgeons of the Atlantic Coast Line Railway, held in Richmond, Va., the following officers were elected: *President,* Dr. John S. McEwan, Ocala, Fla.; *Vice-Presidents* Dr. S. T. Nicholson, Washington, N. C.; Dr. C. E. Moore, Wilson, N. C., and Dr. H. B. Mahoon, Emporia, Va.; *Secretary-Treasurer,* Dr. C. P. Aimar, Charleston, S. C.

Southwestern Medical Association.—At a meeting of this association, which is composed of physicians of Arkansas, Texas, Oklahoma, Missouri, and Kansas, held in Hot Springs, Ark., on October 9 and 10, the following officers were elected: *President,* W. T. Wooten, Hot Springs; *First Vice-President,* W. B. Dorsett, St. Louis; *Second Vice-President,* E. H. Carry, Dallas; *Third Vice-President,* J. H. Barnes, Enid, Okla.; *Fourth Vice-President,* C. C. Nesselrode, Kansas City, Kans.; *Secretary-Treasurer,* F. C. Clark, El Reno, Okla. The convention then adjourned to meet next year in Kansas City, Kansas.

Nacogdoches County (Tex.) Medical Society.—At a meeting in Beaumont on October 9, the physicians of Nacogdoches County organized with the election of the following officers: *President,* Dr. J. H. Barham, *Vice-President,* Dr. R. S. Johnston; *Secretary,* Dr. T. J. Blackwell.

San Joaquin Valley (Cal.) Medical Association.—At the thirty-third annual meeting, held in Merced on October 8, the following officers were elected: *President,* Dr. Henry Hildreth, Delano; *First Vice-President,* Dr. O. W. Stienwand, Selma; *Second Vice-President,* Dr. A. R. Nichelson, Bakersfield; *Secretary,* Dr. R. C. Ross, Fresno; *Assistant Secretary,* Dr. D. H. Trowbridge, Fresno; *Treasurer,* Dr. T. M. Hayden, Fresno.

Obituary Notes.—Dr. William Frederick Dudley of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1886, a member of the American Medical Association, the New York State and Kings County Medical Societies, the American Laryngological, Rhinological, and Otological Society, the New York Academy of Medicine, and the Brooklyn Pathological Society, adjunct clinical professor of diseases of the throat and nose in the Long Island College Hospital, consulting laryngologist to the Norwegian, St. Christopher's, and the Swedish Hospitals, and laryngologist to the Brooklyn and St. John's Hospitals, died at his home on October 22, aged 50 years.

Dr. Arthur Ricketson of New Bedford, Mass., a graduate of Harvard Medical School in 1860, a member of the Massachusetts State and Bristol County Medical Societies, died at his home of paralysis on October 14, aged 77 years. During the Civil War Dr. Ricketson served as assistant surgeon on board the U.S.S. *Nightingale,* on which, while off Pensacola, there occurred an epidemic of yellow fever, resulting in the death of every officer and man, with the exception of Dr. Ricketson, on board.

Dr. Benjamin Ropes Symonds of Salem, Mass., a graduate of Harvard Medical School in 1883, a member of the Massachusetts State and Essex County Medical Societies, and formerly city physician of Salem and a member of the Board of Health, died at his home after a long illness on October 15, aged 55 years.

Dr. Frank R. Wilson of New London, Iowa, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1873, president of the Henry County Medical Society, and a member of the American Medical Association and the Iowa State Medical Society, died at his home of Bright's disease on October 6, aged 60 years.

Dr. William Harmon Buchtel of Denver, Colo., a graduate of the Northwestern University

Medical School, Chicago, in 1866, and a member of the American Medical Association and the Colorado State and Denver County Medical Societies, died suddenly in his office, of heart disease, on October 14, aged 67 years.

Dr. Henry Chavanne of Salem, New Jersey, a graduate of the Jefferson Medical College, Philadelphia, in 1887, and a member of the New Jersey State and Salem County Medical Societies, died at his home on October 16, aged 65 years.

Dr. Hubbard Kavanaugh Adamson of Maysville, Kentucky, a graduate of the New York University Medical College in 1876, died at the Kentucky State Hospital, Lexington, after a long illness, on October 9, aged 59 years.

Dr. Joseph J. Jaches of Brooklyn, N. Y., a graduate of the University of Moscow in 1886, and visiting physician to the Jewish Maternity Hospital, died at his home on October 20, aged 52 years.

Dr. Sydney Howard Carney of Tompkinsville, N. Y., a graduate of the Harvard Medical School, Boston, in 1861, died at his home on October 22, aged 75 years.

Dr. Sidney Davis of Milton, Penn., a graduate of the Medical Department of the University of Pennsylvania in 1877, and a member of the Pennsylvania State and Northumberland County Medical Societies, died at his home on October 17, aged 60 years.

Dr. Francis T. Riley of Waterloo, Iowa, a graduate of the Drake University College of Medicine, Des Moines, in 1890, died at his home after a long illness on October 14, aged 47 years.

Dr. Charles S. Spitler of Mooreland, Indiana, a graduate of the Medical College of Ohio, Cincinnati, in 1892, and a member of the Indiana State and Henry County Medical Societies, died at his home suddenly on October 16, aged 45 years.

Dr. C. E. T. Casto of Parkersburg, W. Va., a graduate of Miami Medical College, Cincinnati, in 1875, and a member of the West Virginia State and Wood County Medical Societies, and the Ohio Valley Medical Association, died at his home on October 14, aged 58 years.

Obituary.

GEORGE MONTGOMERY TUTTLE, M.D.,

NEW YORK.

Dr. George M. Tuttle, who died of angina pectoris on Tuesday of this week, was a gynecologist of note and prominent among medical educators. He was born in Rochester, N. Y., in 1856, and was graduated in arts from Yale University in 1877 and in medicine from Columbia University in 1880. He served a term as interne in the New York Hospital and was then for two years physician in chief of the New York State Emigrant Hospital. He was attending physician at Bellevue Hospital from 1883 to 1889; attending gynecologist at Roosevelt Hospital from 1888 to the time of his death, and consulting physician to the New York Infirmary for Women and Children. From 1885 to 1903 he was professor of gynecology at Columbia University. He was a member of the New York Academy of Medicine, of the medical societies of the County and the State of New York, and of the Society of Alumni of the New York Hospital. Dr. Tuttle was one of the collaborators in the American Text-book of Gynecology, and was an occasional contributor of articles on gynecological subjects to the medical press.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE SOCIETIES—UNIVERSITIES IN RELATION TO MEDICAL EDUCATON—SANATORIUM QUESTIONS—INSURANCE; OPPOSITION OF TRADE UNIONS AND OTHERS—MEDICAL PAYMENT—OBITUARY.

London, October 11, 1912.

After the schools the societies open, and a number of them are now at work. The Royal Society of Medicine began on Tuesday with papers on injury to the semilunar cartilages, one referring to an experience of 449 cases. Yesterday this society had an exhibition of specimens and cases, and others are to be shown this evening. On Wednesday the Hunterian Society began, after a Council meeting, with a communication on "Sleepiness" by Dr. F. Taylor. The United Services Medical Society also began on Wednesday afternoon with a presidential address by Fleet Surgeon Bassett-Smith, C.B., after which Captain Sylvester-Bradley, R. A. M. C., considered the "Disposal of the Sick of a Territorial Force." The Polyclinic and the other post-graduate colleges have each had contributions, demonstrations, or lectures on every day throughout the week. You will see there is no dearth of practical discussion among us; nor is there likely to be.

The Victoria University (Manchester) has an external examiner in medicine on its staff. The present holder of this position is Dr. H. D. Rolleston, the senior physician to St. George's Hospital, London, and he delivered the introductory address at Manchester this year. He is a Cambridge man and took for his subject the relation of universities to medical education, which he dealt with in a broad-minded manner and in various aspects. A Royal Commission and a congress of fifty-three universities of the British Empire have lately devoted some attention to the subject, and many others engaged in education, general and technical, have discussed it. None the less Dr. Rolleston's opinions deserve attention, though I can only refer to some. He is not afraid to admit at the outset that the humanities are not essential to a medical man, although he also admits that in the past most of the eminent members of the profession passed through the classical mill. But he says it hardly follows that their early success was the cause of their later triumphs. On the other hand, some of our immortals owed little or nothing to its influence. Valuable as classical training is, the bulk of medical men pay dearly for the luxury. Most have forgotten their Greek in middle life, except perhaps enough to understand the never ending flow of new, often unnecessary, words ending in *itis* sometimes appended to a Latin noun or modern name. To the ordinary practitioner, then, the direct advantage of classical training is out of proportion to the time devoted to it. Of course, the talk of "the grand old fortifying classical education" is familiar enough to Dr. Rolleston, and he recognizes its value in its place, but he has to acknowledge its comparatively frequent failure to engender the power of writing clear and graceful English. So he says there can be no question that in medical science French and German are incomparably more useful. He suggests a compromise. He would include Latin and Greek in school subjects until about the age of 15½ years, the students to be tested by examination at that stage, the results counting at the

matriculation. Then 2½ years to be given to French, German, English composition, physics, and chemistry, with the necessary mathematics. By this time a pupil (17½ to 18 years old) should pass an examination in the foregoing subjects and begin biology.

I have no doubt the course thus suggested would produce many men of distinction after their further university and hospital careers. But how about the ordinary general practitioner who does not contemplate a university training? Dr. Rolleston did not overlook him altogether, although he was concerned mostly with university men, for whom his proposals are sound enough; but for my part I think these men are well able to indulge their own predilections. For the general practitioner he saw the advantage of a very definite curriculum under the control of the General Medical Council as representing the qualifying bodies, and perhaps the "one portal system" so long advocated. There should not be much difficulty in enforcing this, and the universities having representatives on the examining board, might fairly be asked to give up the right of licensing to practice, and so make their degrees in medicine honorary distinctions only, as in the other faculties.
